Calciophylaxis in the Absence of Renal Disease: Secondary Hyperparathyroidism and Systemic Lupus Erythematosus

To the Editor:

Calciophylaxis is a rare disorder characterized by calcification of small and medium-size arteries, causing thrombosis, tissue necrosis, and painful, nonhealing skin ulcerations. The preponderance of cases occurs in patients undergoing dialysis due to endstage renal disease. Prognosis is generally poor, with one-year mortality ranging from 45% to 80%^{1,2}. A recent report noted that even among nondialysis patients, renal function was moderately to severely impaired in 69% [glomerular filtration rate (GFR) < 40 ml/min]¹. Autoimmune or inflammatory conditions were present in 60%, including systemic lupus erythematosus (SLE), polymyositis, sarcoidosis, hepatitis, ulcerative colitis, rheumatoid arthritis, Sjögren's syndrome, and pemphigus. Various other risk factors are documented, including hyperparathyroidism, elevated serum calcium and phosphate, hypoalbuminemia, obesity, diabetes mellitus, and female sex, and use of warfarin, vitamin D3 analogs and calcium-containing phosphate binders^{1,2}.

Couto, *et al* described a patient with secondary hypoparathyroidism due to vitamin D deficiency, with low calcium/phosphorus product, who developed calciophylaxis in the absence of endstage renal disease³. Case reports of calciophylaxis with normal calcium/phosphorus product as well as normal renal function are limited. We describe a case of calciophylaxis in the setting of normal renal function, in a patient with SLE, secondary hyperparathyroidism due to vitamin D deficiency, and normal calcium/phosphorus product.

A 76-year-old African American woman presented to hospital complaining of worsening severe pain, weight loss, fever, night sweats, and chills. Three months previously she first noted painful lesions near her hips and inner thighs. Initial outpatient punch biopsies showed lipophagic fat necrosis without calcification, the differential favoring lupus panniculitis. The wounds showed limited healing on a course of topical and oral steroids.

Medical history included hypertension, atrial fibrillation, SLE (antinuclear antibodies 54 U/ml, ribonucleoprotein 245 AU/ml, anti-Smith 115 AU/ml), breast cancer status post-lumpectomy and radiation therapy, diverticulosis, and osteoarthritis. Surgical history included bilateral total knee arthroplasties. Medications were alendronate, dicyclomine, fluoxetine, furosemide, gabapentin, hydrocodone/acetaminophen, lidocaine oint-

ment, lorazepam, metoprolol XL, omeprazole, senna/docusate, verapamil ER, warfarin, zolpidem, and a multivitamin.

Examination revealed multiple 4 cm by 6 cm ulcers with central eschars on the thighs (Figure 1). Laboratory data revealed white blood cell count 3.8 thousand/ μ l, hemoglobin 9.2 g/dl, hematocrit 31%, blood urea nitrogen 10 mg/dl, creatinine 0.87 mg/dl, GFR > 60 ml/min/1.73 m², and calcium 8.5 mg/dl. Baseline laboratory results before admission were albumin 3.4 g/dl and phosphorus 2.8 mg/dl. Given concerns about weight loss, the investigations included computed tomography and bone scan, and positron emission tomography scan, which were negative for malignancy.

Dermatology and rheumatology specialists recommended starting prednisone 60 mg on Day 5, although this was soon tapered to 30 mg. A deep tissue biopsy was discussed, but not performed until Day 15, and showed calciophylaxis (Figure 2). Plaquenil was added, and prednisone was tapered to 10 mg. On Day 18 laboratory results revealed calcium 7.9 mg/dl (albumin-corrected 9.1 mg/dl), phosphorus 2.7 mg/dl, albumin 2.5 g/dl, 25-hydroxy vitamin D 22.7 ng/ml (reference 32–100), and 1,25-hydroxy vitamin D 30.6 pg/ml (reference 15.9–55.6), and on Day 19 intact parathyroid hormone 121.4 pg/ml (reference 14–72), despite the patient taking calcium/vitamin D supplement from Days 10 to 20. On Day 22 she was switched from warfarin to enoxaparin for atrial fibrillation.

Parathyroidectomy was discussed but not pursued, as serum calcium concentrations were normal. The decision was made to transfer care to an outside facility more familiar with nonuremic calciophylaxis; the patient's response to treatment is unknown.

Calciophylaxis in patients without renal impairment occurs rarely. A review by Nigwekar, *et al* of 36 nonuremic cases included only one occurrence of vitamin D deficiency and no patient with SLE⁴. Our case, along with that of Couto, *et al*, represents the rare occurrence of calciophylaxis in a patient with secondary hyperparathyroidism due to vitamin D deficiency. The calcium/phosphate product differed in these cases, but it is well known that serum calcium and phosphate levels do not correlate to disease severity^{1,2}. To our knowledge, this also represents the first case of calciophylaxis occurring in a patient with SLE and normal renal function.

The exact cause of our patient's disease is unknown. Several other risk factors were present, including female sex, obesity, and warfarin use. She also had a history of breast cancer. However, she was not treated with chemotherapy, and an extensive investigation ruled out metastatic disease.

Many physicians are not familiar with nonuremic cases of calciophylax-

is. It required a protracted hospital stay, numerous tests, and collaborative management from various specialties to reach a diagnosis for this patient. Although prompt diagnosis is important, in order to modify risk factors, clear guidelines for treatment are lacking. Varying success rates exist for parathyroidectomy, surgical debridement, and hyperbaric oxygen therapy^{1,2}. Recently, sodium thiosulfate has been used, particularly in a patient with normal renal function⁵. We add this case to the short list of reports of calciphylaxis occurring in the absence of renal disease, hoping to better define the disease etiology and promote awareness.
