Initial jLS CTP results

Abstract

Objective: To perform a comparative effectiveness feasibility study in juvenile localized scleroderma (jLS), using standardized treatment regimens (consensus treatment plans, CTPs).

Methods: A prospective, multi-center 1-year pilot observational cohort study was performed by Childhood Arthritis and Rheumatology Research Alliance (CARRA) localized scleroderma workgroup members. Active, moderate to severe jLS patients were treated with one of three CTPs: methotrexate alone, or in combination with intravenous (30 mg/kg/dose for 3 months) or oral corticosteroids (2 mg/kg/day tapered off by 48 weeks).

Results: Fifty patients, with demographics typical for jLS, were enrolled, and 44 (88%) completed the study. Most had extracutaneous involvement. Patients improved in all three CTPs, with $\geq 75\%$ having a major or moderate level of improvement compared to baseline.

Damage accrued in some patients. Major deviations from prescribed regimen resulted from medication intolerance (n = 6, 14%) or treatment failure (n = 11, 25%); failures occurred in all three CTPs. Significant responses to treatment were demonstrated by LS skin scoring measures and overall physician assessments, with differences in response level identified in some patient subsets. Baseline disease activity level, LS subtype, skin disease extent, and extracutaneous involvement were associated with response differences.

Conclusions: This study demonstrates the feasibility of conducting jLS comparative effectiveness studies. The CTPs were found to be safe, effective, and tolerable. Our assessments performed well. As damage is common and may progress despite effective control of activity, we recommend initial treatment efficacy be evaluated primarily by activity measures. Potential confounders for response were identified that warrant further study.

Initial jLS CTP results

Introduction

Localized scleroderma (LS), which includes circumscribed morphea and linear scleroderma, is an autoimmune disease characterized by inflammation and fibrosis [1, 2]. It is the most common childhood form of scleroderma, and pediatric onset has worse morbidity than adult disease [3, 4]. Morbidity includes uveitis, seizures, arthropathy, and growth disturbances such as limb and facial hemiatrophy. Functional impairment is found in 28-56% of jLS patients [5-9].

Treatment focuses on controlling inflammation, as effective treatment options for fibrosis are limited. Most North American and European pediatric rheumatologists, and many other physicians, agree on the use of methotrexate (MTX) to treat moderate to severe disease [10-14]. A single randomized, double blind, placebo controlled study evaluating the efficacy of MTX in 70 jLS patients, who received an initial oral corticosteroid (CS) course, demonstrated a higher response rate among patients in the MTX compared to placebo arm (67.4% vs 29.2%, respectively) [15]. Many case reports also support MTX's efficacy [16-22]. However, physicians differ regarding MTX dosing, route, and duration, need for CS, and CS regimen [10, 23]. In a survey of North American pediatric rheumatologists asking their preference for treating jLS with a standardized MTX-based regimen, 31% preferred MTX monotherapy, 36% MTX with intravenous pulse CS, and 23% MTX with oral CS [23]. Given the lack of data to support the superiority of one regimen over another, there is clearly a need for comparative effectiveness studies in jLS.

To assess feasibility and methodology for comparative effectiveness studies in jLS, we evaluated the safety and tolerability of three MTX-based regimens (consensus treatment plans, CTPs) [23] in a pilot one-year open-label study of 50 patients initiating treatment for active jLS.

Initial jLS CTP results

We identified the frequency of and reasons for deviation from the CTP, adverse events associated with therapies, and response to treatment by several clinical assessments.

Methods

Study protocol:

The LS workgroup of the Childhood Arthritis and Rheumatology Research Alliance (CARRA) conducted this study; details on the development of the study and CTP choice are described elsewhere [24]. Each participating site (n = 10) obtained institutional ethics approval for both the study itself and the informed consent form, which included our intent to publish the results of the study and measures to protect confidentiality. The written consent was signed by either the patient or by the patient's parent/guardian with written or verbal assent of the patient, as appropriate for age. De-identified data were analyzed at Hackensack University Medical Center, the coordinating center, under ethics approval number Pro00001481.

Inclusion and exclusion criteria for participation in the study are shown in Table 1 [23, 25, 26]. At entry, patients started treatment with one of three MTX- based CTP (Figure 1A): MTX monotherapy (CTP A, 1mg/kg/week, maximum 25 mg; same dose for all CTPs), MTX with intravenous (IV) CS (CTP B; IV CS 30 mg/kg/dose, maximum 1000 mg, either 3 consecutive days/month x 3 months or 1/wk x 12 weeks) or MTX with oral CS (CTP C; prednisone or prednisolone 2 mg/kg/day, maximum 60 mg, divided bid, tapered to 1 mg/kg/d by 8 weeks, 0.5 mg/kg/d by 16 weeks, 0.25 mg/kg/d by 24 weeks, and off by 48 weeks). Subcutaneous administration of MTX was recommended. Choice of CTP was decided by treating physician and the patient's family (discussed in [24]). Patients were monitored at 6 study visits over 1 year: baseline, 2, 4, 6, 9, and 12 months, with recommended visit windows of \pm 1 month. At the initial visit, demographic information including subtype as defined by Padua criteria [24], past medical history, treatment history for jLS, and family history were collected. At subsequent

Initial jLS CTP results

visits, medication history and adverse events (AE) were recorded. AE were graded according to the Common Terminology Criteria [27]. Laboratory studies were done at the discretion of the treating physicians. Most of the data was entered into a web-based registry (i2b2 CARRA Legacy Registry); remaining data were captured in a database at the PI's site. There was an optional biorepository substudy, banking blood samples for future studies.

The same physician evaluated a given patient at all study visits to avoid interrater variability. Evaluations included modified localized skin severity index (mLoSSI), LS Damage index (LoSDI), and measures we recently developed [23, 28, 29]. The mLoSSI divides the body into 18 anatomic sites for scoring, and is calculated as the sum of disease extension (scored 3 if present), erythema (scored 0 to 3, severe), and skin thickening of the lesion edge (scored 0 to 3, severe) in all affected sites [28, 30]. Building from the mLoSSI, the LS cutaneous activity measure (LSCAM) also scores additional variables that were found associated with activity in another study [31]. LSCAM is calculated as the sum of disease extension, erythema, maximum lesion skin thickening, violaceous color, tactile warmth, and waxy white or yellow; erythema and skin thickening are scored 0 to 3 (severe), the other variables 0 or 1 if present [23]. The LoSDI and LS cutaneous damage measure (LSDam) sum dermal atrophy, subcutaneous atrophy, and dyspigmentation across affected sites [29]. The LSDam also scores maximum lesional skin thickening. Variables in LoSDI and LSDam are scored 0 to 3 (severe), with scoring examples provided in LS Scoring Atlas [23].

Extracutaneous involvement (ECI) considered secondary to LS was scored as 0 or 1 if present; the list of scored items was generated based upon literature [23, 32, 33]. Joint involvement included arthritis (joint swelling) and contractures (limited range of joint motion without swelling). Growth difference was scored if the clinician considered it to be obvious and significant, and included limb girth and length differences, and facial and truncal hemiatrophy.

Initial jLS CTP results

Skin activity scoring was performed at all visits, while skin damage and ECI scoring were assessed at visits 0, 6, and 12-months. Efforts to standardize scoring are described elsewhere [24].

Physician global assessment of disease activity (PGA-A) and Physician global assessment of disease damage (PGA-D) were scored on 0-10 (high) Likert scales. PGA-A was scored at every visit; PGA-D at 0, 6, and 12-month visits. Physician assessment of overall disease status compared to baseline visit (Δ -disease status), and physician assessment of overall activity status compared to baseline visit (Δ -**activity** status) were scored on a 7 level Likert scale from major improvement (3) to major worsening (-3) at the last visit. These global assessments included consideration of extracutaneous involvement. No guidelines were provided on scoring these assessments, instead each study investigator determined how to score them based upon their clinical evaluation and judgment. Patients and/or their parents were asked to complete health-related quality of life assessments (HRQOL) at visits 0, 6, and 12-months (Table 3 [34-38]).

Protocol deviations:

Changing the route of MTX administration, having a temporary reduction or lapse in taking MTX (≤ 2 weeks), and missing a prednisone taper target because of a delayed study visit were considered minor deviations. Stopping treatment (by physician, patient, or family), prolonged change in specified dose or duration of CTP medication(s), and/or using a immunomodulator not specified by initial CTP were considered major deviations. Patients who withdrew or failed to follow-up were scored as drop-outs and not included in response analysis. Treatment failure (TF) was defined as inadequate response to the initial regimen leading to treatment with additional CS and/or non-CTP specified immunomodulator.

Initial jLS CTP results

Data analysis:

Data were summarized using frequencies (percent) for categorical variables and median (with interquartile range) of continuous variables. Patient response was analyzed based upon intent to treat and censored for treatment failures. Comparisons across groups, where appropriate, were performed using Chi-square or Fisher's exact tests for categorical data and Wilcoxon-rank sum tests or sign rank tests for continuous, non-parametric data. Normality was assessed using the Shapiro-Wilks test ($p < 0.001$). Spearman correlation was performed to examine correlations between activity, damage, and improvement in scores across visits as well as lesion and disease characteristics. We used the most recent non-missing data when comparing activity or damage scores to a previous visit. An alpha of 0.05 was used to assess significance; given the small sample, we also noted variables with a p -value < 0.1 . Data were analyzed using SAS v 9.4.

Results

Patient characteristics:

Patients were enrolled into all three CTPs, achieving the target enrollment of 50 patients (Figure 1). Most patients were Caucasian (46, 92%) and had linear scleroderma subtype (30, 60%). The median age of disease onset was 9.6 years (IQR 6.1, 11.7), and disease duration 13 months (IQR 6, 53.8). Forty-one patients (82%) were newly diagnosed and naïve to systemic immunosuppressants; the other 9 patients had a disease relapse off prior systemic treatment. Thirty-seven (74%) patients had ECI, primarily growth difference (24, 48%) and/or joint contractures (20, 40%).

Six patients discontinued treatment before the last visit (drop-outs, Figure 1A). The remaining 44 patients completed the study and were analyzed for treatment response and adverse events (AE). CTP groups differed in the number of affected anatomic sites ($p = 0.021$),

Initial jLS CTP results

and subtype frequency, growth disturbance, and ANA positivity ($p < 0.1$) (Table 2). No differences were found for age, disease duration, race, ethnicity, ECI, or family history of autoimmune disease (Table 2 and data not shown).

Safety and tolerability of CTPs:

Six patients (14% of patients completing last visit) had a major deviation from the CTP because of medication intolerance (Figure 1A), including one (2%) grade 3 AE, a hospitalization for gastroenteritis and dehydration, considered unrelated to the CTP (B). Twenty-one patients (48%) had a grade 2 AE, with no difference in frequency across groups. The most common grade 2 AE were gastrointestinal problems ($n=11$, 25%), which were managed by ondansetron treatment ($n = 5$), changing route of administration ($n = 2$), reducing dose ($n = 2$), or discontinuing MTX ($n = 3$). Other grade 2 AEs were mood problems ($n = 5$, 11%), infection ($n = 3$, 7%), laboratory abnormalities ($n = 3$, 7%), and one each of seizure recurrence, hair thinning, lip and nasal ulcer, and blurred vision. One patient discontinued IV CS because of access difficulties. Patients who experienced treatment failure (TF) and received additional medication(s) had more grade 2 AE (82% versus 36% for non-TF, $p = 0.009$). Grade 1 AE were more frequent in the oral corticosteroid regimen (CTP C, $p = 0.005$), most commonly weight gain or Cushingoid features ($n= 13$, 29.5%), gastrointestinal problems ($n=10$, 23%), and mood problems ($n=4$, 9%).

Response to CTPs:

Nearly all patients improved compared to baseline by two physician global assessments (Δ -disease status, Δ -activity status). Δ -activity status rated 43 of 44 (98%) patients as improved, versus 40 (90%) by Δ -disease status (Figure 1B). Both assessments rated a patient who had disease extension and return of induration at 9 months as worsened. The Δ -disease

Initial jLS CTP results

status rated an additional three patients as worsened including one with seizure recurrence at 12 months without cutaneous activity signs (linear scleroderma of the head subtype), and two who developed more damage features (worsening facial or other growth difference) with no, or minimal, residual skin disease activity.

While this pilot study was not powered to assess efficacy, we analyzed the response of patients in each CTP to provide information on our assessments and identify potential confounders. PGA-A, mLoSSI, and LSCAM scores decreased from baseline to last visit in all CTP groups when analyzed based upon intent to treat and censored for treatment failures (Table 3). PGA-D, LoSDI, LSDam, and several patient/parent health related outcome scores did not differ from baseline to last visit (Table 3).

To track response across the 6 visits, we examined if and when patients achieved a PGA-A score of 0. PGA-A = 0 occurred in 42% of CTP A, 44% of CTP B, and 67% of CTP C patients (Table 4A). When patients with treatment failure were excluded, percentages increased to 50% (A), 59% (B), and 75% (C) (Table 4A). Patients in CTP C (MTX plus oral CS) appeared to reach 0 sooner, but these differences were not significant. Patients in CTP C had lower baseline LSCAM and LSDam scores than patients in CTPs A and B ($p < 0.05$, Table 3A); mLoSSI or LoSDI scores were not different across groups (Table 3A). The lower cutaneous scores for patients in CTP C may reflect their having less extensive skin disease (Table 2).

Patients were stratified into four levels of baseline PGA-A scores: 1-2, 3-4, 5-7, and ≥ 8 to explore if the baseline PGA-A score affected the likelihood of reaching PGA-A=0. Higher baseline PGA-A scores were associated with both lower likelihoods and slower rates of achieving PGA-A=0. Two-thirds of non-TF patients who had a baseline PGA-A score of ≤ 7 reached 0 within 12 months, compared to 13% of patients with a PGA-A of 8 or above ($p = 0.045$, Table 4B).

Initial jLS CTP results

Treatment failures:

Eleven patients were considered to have experienced treatment failure (TF) and received additional treatment: IV CS (n=10) and/or mycophenolate mofetil (MMF, n=8). A larger percentage of patients experienced TF in CTP A (n=4, 33%) and CTP B (n=6, 25%) than CTP C (n=1, 12.5%), but these differences were not significant (Figure 1B). Four patients enrolled in CTP A (methotrexate monotherapy) received IV CS, and six patients in CTP B received longer IV CS courses; 1 also received oral CS. Eight patients (1 CTP A, 6 CTP B, 1 CTP C) received MMF, all concurrently with MTX. Median time to TF was at the 4-month visit (median 116 days), range 2-9 month visit (97-302 days).

At last visit, most patients who experienced TF were rated as having a moderate level of improvement (Δ -activity, n=6, 54.5%) versus the major level of improvement given to most non-TF patients (n=18, 56.3%). PGA-A, mLoSSI, and LSCAM scores decreased from baseline to last visit in patients who experienced TF ($p < 0.001$, Table 5), but these patients did not experience as much improvement as non-TF patients. At last visit, they had higher PGA-A, mLoSSI, and LSCAM scores than non-TF patients ($p = 0.011, 0.003, < 0.001$, respectively, Table 5). At the last visit, PGA-D scores were also higher in TF than non-TF patients ($p = 0.003$, Tables 5). Patients who experienced TF were more likely to be non-white race, and have mixed morphea, generalized morphea, or pansclerotic morphea, ECI, joint involvement, and truncal lesions (Table 5). There was a trend towards significance for limb involvement, more extensive skin disease, higher frequency of growth disturbance, older age of disease onset, ANA positivity, and family history of a rheumatic disease ($p < 0.1$) (Table 5).

Discussion:

Initial jLS CTP results

This is the first prospective comparative effectiveness study of three different methotrexate-based regimens for jLS. The study aims were to assess the safety and feasibility of the three standardized regimens and evaluate our assessment tools. Our prior survey of North American pediatric rheumatologists demonstrated the need for comparative effectiveness studies, as responders were almost equally divided on their choice of these 3 MTX-based CTPs [23]. Our investigators similarly showed distinct treatment preferences with half the sites choosing a single CTP to treat all of their study patients [24]. As the physician and parent/patient jointly selected the treatment CTP, some of these choices reflect family preference with at least 3 families opting for MTX monotherapy over their physician's recommendation for a CS-associated CTP.

All three CTPs were found to be safe, generally well tolerated, and effective, with over half the patients having PGA-A=0 by their last visit. However, only about half completed the CTP they initially started; dropouts and adverse events accounted for 52% of the deviations, and treatment failures the remainder. The frequencies of AE for MTX and CS were similar across the CTPs. Most AEs were managed by supportive care or brief pauses in treatment. Six patients (14%) had their CTP regimen changed because of intolerance. This frequency is higher than was reported in the corticosteroid-based RCT of MTX [15], possibly reflecting higher methotrexate dose (1 mg/kg/dose vs 15 mg/m², potentially 2x greater for small child), route of administration, differences in CS regimen including route, longer and higher oral prednisone dose, and/or patient characteristics

Most who experienced treatment failure received mycophenolate mofetil (MMF), all in combination with MTX. Our group had previously developed an MMF-based CTP that allowed for use of MMF with or without MTX [24], but it was not included in the current study. The high frequency of CTP failures suggests that additional standardized treatment regimens are likely

Initial jLS CTP results

needed for comparative effectiveness studies, including evaluating the efficacy of MMF separate from MTX, and examining biologics or other disease modifying anti-rheumatic drugs.

Several physician scores and skin activity measures were used to assess treatment response. We found limitations in the physician assessment of overall disease status compared to baseline (Δ -disease status) because it encompasses damage as well as activity status. Three patients developed worsening of extracutaneous features by their last visit, and although all were rated as improved by Δ -activity status, all were scored as having a worsened disease status compared to baseline. These patients demonstrate that damage can progress despite effective control of disease activity. We therefore recommend activity and damage should be separately assessed for jLS, with initial treatment efficacy evaluated primarily by activity measures.

We detected differences between subpopulations, suggesting that our assessments are sensitive enough to use in comparative effectiveness studies. Our LS cutaneous activity measure (LSCAM) includes more variables than found in the mLoSSI, the model for our measure. Both measures detected significant changes in skin scores between first and last visit; the LSCAM was also able to detect differences between CTPs and showed a wider range of scores in the treatment failure patients than the mLoSSI. Higher baseline PGA-A scores were associated with a slower and lower rate of response, especially if the baseline PGA-A score was 8 or higher. Our analysis of the TF- patients identified additional variables associated with poorer response including truncal lesions, ECI, joint involvement, non-white race, and mixed morphea subtype. More extensive skin involvement, limb involvement, growth impairment, and ANA positivity approached significance. Further evaluation is needed to determine if some

Initial jLS CTP results

of these variables are confounders that should be considered when designing treatment trials or evaluating response.

Because this was a pilot study, it was not powered for determining the relative efficacy of the CTPs. There was a trend towards a faster and higher rate of response in one of the CTP groups, which may reflect differences in disease severity and pattern between groups. Patients in the CTPs associated with poorer response had higher LSCAM scores at baseline, more extensive skin disease, and higher frequency of mixed morphea subtype, growth disturbances ($p < 0.05$), and likelihood of joint involvement ($p < 0.1$). Some of these variables were also identified in patients who experienced treatment failure, suggesting they may represent prognostic features that are confounding the relationship between treatment and response. In a larger sample, case control methods could be used to match subjects according to variables associated with disease severity/ activity in order to more effectively evaluate the efficacy of the CTPs without selection bias.

Study limitations include the large variation in time of the “12-month” study visit, with several patients seen outside of the recommended window of 12 ± 1 month. This is to be expected in prospective observational studies, where visits are completed according to requirements for care rather than the more rigorous schedule of standardized treatment trials. Another limitation is the absence of serological biomarkers to identify or quantify disease activity. We performed several clinical assessments in tandem to improve our accuracy of clinical scoring. However, physicians may be biased towards a given CTP’s efficacy, so use of assessors blinded to the chosen CTP may be advisable.

Our study findings add substantially to the understanding of treatment strategies for jLS patients. All three CTPs were found beneficial, yielding tangible and significant improvements in disease activity. Our cutaneous activity measure and physician assessments could identify

Initial jLS CTP results

both changes during the course of treatment and differences in response between some patient subsets. More studies are needed to assess the reliability, validity, and performance of our LSCAM measure compared to mLoSSI. Further study is needed to determine if these clinical outcome measures are sensitive enough to detect differences in relative efficacy between treatments. Studies are also needed to develop biomarkers to enhance monitoring of response.

The widespread occurrence of ECI in our cohort (>70%) demonstrates that jLS is a serious disease with a high potential for severe morbidity. All patients who experienced treatment failure had ECI; at the end of the study they had higher LSCAM and physician global damage scores. In addition, despite nearly all patients having a marked reduction in disease activity level, damage scores did not improve, and in some patients worsened. Our findings suggest that patients with a larger disease burden (skin and other tissues) are at risk for more damage and require more treatment for disease control. It may be worthwhile considering treat-to-target strategies for jLS as has been proposed for rheumatoid arthritis [39]. Larger, more robust comparative effectiveness studies are needed to objectively identify optimal treatment strategies that minimize disease burden, medication intolerance, and damage progression. Findings from this study should help inform the development of such studies. We expect an iterative process that will improve our ability to optimize therapy and long-term outcome for these patients.

Acknowledgements

This study was funded primarily by an innovative research grant from the Arthritis foundation (PI: SL). CARRA provided additional funding for data analysis (publication grant, PI: SL) and in-kind resources to support management and maintenance of the registry for the study, online meetings, and face-to-face meetings at annual meetings of CARRA and ACR.

Initial jLS CTP results

Figure legends

Figure 1. Schematic of the 50 patients who were enrolled in the jLS CTP Pilot Study.

A. The three CTPs are depicted by the blue, pink, and green rectangles: A = MTX monotherapy;

B = MTX with IV CS (methylprednisolone, 3 pulse doses per month x 3 months); C = MTX with daily oral CS (prednisone or prednisolone; beginning at 2 mg/kg/day tapering off by 48

weeks), respectively. All three CTPs included the same methotrexate dose (1 mg/kg/week, maximum 25 mg); subcutaneous route of administration was preferred. The numbers and

percentages in the rectangles refer to the patients enrolled in each CTP, and who remained in

their starting CTP after accounting for drop-outs, adverse events (AE) that led to a major

deviation from the CTP, and treatment failures (TF). The numbers in the circles indicate the

number of patients who dropped-out, had an AE, or were considered to be a TF. Study dropouts

occurred in CTP A after the 2-month visit (n=1) or 6-month visit (n=2), in CTP B after baseline

visit, in CTP C after baseline visit (n=2). The medication changes related to AE and TF are

shown in the boxes to the right of the circles. The numbers in these boxes refer to the number of patients that had this change.

B. Bar charts below each CTP indicate the physician assessment of activity status compared to

baseline scores (Δ -activity status, blue, pink, or green bars) or physician assessment of disease

status compared to baseline scores (Δ -disease status, black bars) rating of the 44 patients who

completed the last visit based upon intent to treat (excludes drop-outs, but includes AE and

TF). The X-axis indicates the percentage of patients who received that rating.

AE = adverse event leading to a major deviation from the CTP; CS: corticosteroid; CTP:

consensus treatment plan; Dc = discontinue; Improve = improvement; IV: intravenous; jLS =

juvenile localized scleroderma; Mod = Moderate; MTX: methotrexate; No. = number; TF =

Initial jLS CTP results

patient judged to have experienced treatment failure by physician, necessitating treatment in addition to that specified by CTP; Worse = worsening.

Table 1: jLS CTP Study Entry Criteria: Inclusion, Exclusion, and Active Disease criteria

Inclusion Criteria:

1. Localized scleroderma diagnosed by a Pediatric Rheumatologist or Pediatric Dermatologist according to Padua Preliminary Classification criteria; these criteria exclude eosinophilic fasciitis [24]
2. Fulfill active disease criteria, listed below
3. Moderate to severe disease severity that warrants systemic therapy in the opinion of the treating physician
 - a. This includes all subtypes that involve deeper tissue(s), extensive skin involvement, and/or extracutaneous involvement
4. Age <18 years at onset of disease
5. Age <21 years at onset of treatment

Exclusion criteria:

1. Treated with systemic corticosteroids in the prior two weeks
2. Treated with methotrexate or mycophenolate mofetil within the prior three months
3. Another defined systemic rheumatic disease (e.g., systemic sclerosis)
4. Intolerance to study medications

Active disease criteria**Group 1: One item suffices**

1. New lesion(s) within the prior 3 months, documented by clinician
2. Extension of an existing lesion within the prior 3 months, documented by clinician

- a. Lesion extension observed in serial photographs or tracings, or detecting $\geq 30\%$ difference in lesion size (maximum length x width)
- 3. Documentation of active or progressive deep tissue involvement
 - a. Can be by clinical examination, photographs, MRI, or ultrasound.
- 4. Erythema of moderate or severe level in lesion or an erythematous lesion border
 - a. Rating of erythema scoring level based upon LS Scoring Atlas
- 5. Violaceous lesion or border color

Group 2: Need at least two items

- 1. Patient or parent report of new lesion OR extension of existing lesion occurring within the prior 3 months
 - a. This criterion ONLY applies for new patients (i.e., first visit to clinician's office).
- 2. Mild erythema of lesion
 - a. Rating of erythema scoring level based upon LS Scoring Atlas
- 3. Severe or moderate induration of lesion border
 - a. Assessed according to modified Rodnan Skin Scoring (mRSS) scoring levels [25]
- 4. Tactile warmth of the lesion
 - a. Examiner appreciation of temperature difference based upon comparison to control site (unaffected contralateral site if available).
- 5. Worsening hair loss in scalp, eyebrow, or eyelashes; documented by clinician
- 6. Elevated creatine kinase level in the absence of other source
- 7. Lesion biopsy showing active disease (based upon pathologist report. Typically would be presence of lymphocytes, plasma cells, eosinophils, or other white blood cell)

Table 1: Study entry criteria used for the jLS Consensus Treatment Plan (CTP) Pilot study.

These criteria were previously developed [23] for the purpose of directing comparative effectiveness studies in jLS and were not intended to qualify or disqualify patients for any specific treatment. The LS Scoring Atlas was generated by the LS workgroup of CARRA and contains photographs of patient lesions demonstrating the different visible scored features; $\geq 80\%$ consensus agreement by workgroup members was required for the photograph to be included in the atlas [23]. Suggested modifications of these entry criteria for future studies are described elsewhere [24].

	Family History of An Autoimmune Disease (%)	21 (48.8)	6 (50%)	10 (45.5%)	5 (56%)	NS

Initial results jLS CTP

p-values for differences across the 3 CTPs are shown in last column. Significant p-values are bolded, values that approached significance are in italics.

Superscript numbers in first column indicate differences between patients in one CTP compared to those in the other two.

Differences between patients in CTP C versus CTPs A and B: ¹: P <0.05, ³: P =0.08. Differences between patients in CTP C versus

CTPs A and B: ²: P <0.05

Table 2: Demographics of the 44 patients who completed and were on treatment at the last study visit.

The last visit was the “12” month visit for 43 patients, and “9” month visit for 1 patient. For two patients, the chronological time of their “12” month visit was at 274 or 295 days. We therefore decided to include a subject whose last study visit was the “9” month visit which occurred at a chronological time of 283 days. This patient lived far from the study site, did not make the “12” month visit, but did have a later follow-up visit.

Extracutaneous involvement was scored based on presence at any time during the study. Growth disturbance refers to limb girth or length difference, or facial or trunk hemiatrophy. Joint involvement refers to arthritis (swollen joint) or joint contracture. Other extracutaneous involvement were headache (4), seizure (1), pseudopapilledema (1), Raynauds phenomenon (2), muscle spasm (2), and dental crowding (1). The number of anatomic sites is based upon the divisions used for the LS

Initial results jLS CTP

Cutaneous Activity measure; the body is divided into 19 sites: scalp, face, neck, chest, abdomen, back, buttock, arm (right/left), forearm (right/left), hand (right/left), thigh (right/left), lower leg (right/left), and foot (right/left).

The p values on the “Race” and “Subtype” rows refers to the significant difference found in the distribution of all of the listed races or subtypes, respectively. Circumscribed morphea subtype was also found to differ between patients in CTP C versus CTPs A and B ($p = 0.004$).

Family history of an autoimmune disease includes rheumatic diseases and additional autoimmune diseases such as celiac disease, type 1 diabetes mellitus, and multiple sclerosis. Thirty-eight patients were evaluated for ANA positivity, 40 patients had an initial ESR or CRP test done. ANA = anti-nuclear antibody; ESR/CRP = sedimentation rate or C-reactive protein; no. = number; NS = non-significant.

Table 3: Change in cutaneous, physician, and parent/patient scores from baseline to last visit in each CTP.

A. Intent to Treat (n=44)

Measure	Visit	All Patients (n = 44)	A: MTX (n = 12)	B: MTX + IV CS (n = 23)	C: MTX + PO CS (n = 9)

Impact of rheumatic	Baseline	1 (0, 2)	0 (0, 1)	1 (0, 5)	1 (0, 3)

disease	Last	1 (0, 2)	1 (0, 1)	2 (1, 2)	0.5 (0, 1.5)
---------	------	----------	----------	----------	--------------

Significant changes in scores from baseline to last visit are indicated in “All Patients” and “CTP” columns by: ^ = $p < 0.01$; * = $p < 0.001$.

Superscript numbers in Visit column indicate differences in scores between patients in CTP C versus those in CTPs A and B: ¹: $p < 0.05$.

Table 3: Change in cutaneous, physician, and parent/patient scores from baseline to last visit in each CTP based upon intent to treat (A) or censored for treatment failures (B).

Median scores of study assessments at baseline and last study visit are shown. Interquartile ranges are in parentheses. Patients who dropped out or discontinued treatment prior to their 9-month visit [$n = 6$] were not included. Patients who deviated from their initial CTP because of adverse event, but were able to continue on systemic treatment were included in 3A, while those who deviated because of treatment failure were not included in 3B.

The mLoSSI and LSCAM score cutaneous activity features, while the LoSDI and LSDam score cutaneous damage features. Overall global health refers to the parent or patient question: ‘How do you rate your child’s health?’ range excellent [5] to very poor [1]. If the child was answering the question, then the question was reworded to focus on the patient’s point of view. Impact of rheumatic disease refers to the parent or patient question: ‘Considering all the ways that your child’s rheumatic condition affects your child, rate how your child is doing’, 0 = no impact, 10 = highest impact); If the child was answering the question, then the question was reworded to focus on the patient’s point of view.

Additional health related quality of life measures asked of parents or patients included global pain ('How much pain do you think your child had because of his/her rheumatic condition in the past week?') and the Childhood Health Assessment Questionnaire (CHAQ) [reference 33], neither of which were found to differ significantly between the baseline and last visit. Other collected measures were PedsQL general, PedsQL rheumatology, PedsQL Family Impact, and childhood dermatology life quality index [references 34 - 37].

CS: corticosteroid; CTP: consensus treatment plan; IQR: interquartile range; IV: intravenous; LoSDI: Localized Scleroderma Damage Index; LSCAM: Localized Scleroderma Cutaneous Activity Measure; LSDam: Localized Scleroderma cutaneous Damage measure; mLoSSI: modified Localized Scleroderma Severity Index; MTX: methotrexate; n: number of patients in each category; PGA-A: Physician global assessment of disease activity; PGA-D: Physician global assessment of disease damage; PO: oral.

Initial results jLS CTP

Table 4: The total number of patients who achieved a PGA-A score of 0 at each study visit after baseline.

A. Patients Stratified by Initial CTP Regimen

CTP	No.	Visit Month					Overall No. (%)
		2	4	6	9	12	
Intent to Treat							
A	12	0 (1)	1 (3)	2 (1)	3 (0)	5 (1*)	5 (42)

3 or 4	14	2 (1)	4 (6)	5 (2)	8 (2)	9 (0)	9 (64)
5-7	10	3 (2)	3 (1)	5 (1)	5 (2)	6 (0)	7 (70)
8+	5	0 (0)	0 (1)	0 (3*)	1 (3*)	1 (3*)	1 (13)

Visit data censored due to AE requiring deviation from a CTP regimen (n=3) or treatment failure (n=1) are indicated by an asterisk (*).

Table 4: The total number of patients who achieved a PGA-A score of 0 at each study visit after baseline.

To track improvement in PGA-A scores across visits, the total number of patients who had achieved a PGA-A of 0 at each study visit after baseline were counted. Patients are stratified by initial CTP regimen (A) or baseline (initial) PGA-A score (B). The total number of patients that had achieved a PGA-A score of 0 by this visit are listed and the number of

Initial results jLS CTP

patients who were missing at each visit *and* had not yet reached a PGA-A score of 0 is noted in parentheses. Follow-up visits were specified to occur within 1 month of target time of 2 months, 4 months, 6 months, 9 months, and 12 months.

A. Patients stratified by initial CTP regimen.

The top panel shows the values for all patients who were receiving systemic immunosuppressive treatment at last study visit based upon the initially prescribed CTP; the bottom panel excludes the 11 patients who were treatment failures. A number of patients in CTP B missed their 4-, 6-, and/or 9-month visits; however, at 12-month visit, the only missing data were due to censoring. In CTP A, data from 1 patient was censored at the 12 month visit because of drop-out due to treatment failure; this patient is only represented in the top panel. In CTP B, data from 2 patients were censored at 6-month visit, and in CTP C data from 1 patient was censored at 9-month visit, because of treatment discontinuation secondary to adverse events.

B. Patients stratified by baseline PGA-A score.

The top panel shows the values for all patients who were receiving systemic immunosuppressive treatment at last study visit based upon the initially prescribed CTP; the bottom panel excludes the 11 patients who were treatment failures. Data from one patient in the baseline PGA-A 5-7 score group was censored at the 12-month visit in the top panel; Data from 3 patients in the baseline PGA-A 8+ score group were censored at the 6 month visit in both panels.

CTP: consensus treatment plan; PGA-A: physician global assessment of disease activity.

Table 5: Characteristics of patients who were treatment failures

	No TF	TF	P-value
Number of Patients	33	11	
CTP A	8 (24%)	4 (36%)	NS
CTP B	17 (51.5%)	6 (55%)	NS
CTP C	8 (24%)	1 (9%)	NS
Age at enrollment (years), median (IQR)	13 (9.4, 14.1)	12.1 (9.8, 15.1)	NS
Age of Onset (years), median (IQR)	9.03 (5.7, 10.6)	10.1 (9.2, 13.5)	0.076
Disease Duration at enrollment (months), median (IQR)	24 (6.50, 76.0)	10 (6, 13.0)	NS

PGA-D:	Baseline, median (IQR)	4 (3, 5)	5 (4, 7)	NS
	Last, median (IQR)	3 (2, 4)	5 (3, 7)	0.003
ANA positivity		14 (52%)	9 (82%)	<i>0.087</i>
Family history of Rheumatic Disease		11 (34%)	7 (64%)	<i>0.090</i>

p-values for differences between patients who experienced treatment failure versus those that did not are shown in last column. Significant p-values are bolded, values that approached significance are in italics.

Significant changes in scores from baseline to last visit are indicated in “No TF” and “TF” columns by * ($p < 0.05$), ** ($p < 0.001$).

Table 5: Characteristics of patients who were treatment failures.

The 11 patients who experienced treatment failure were compared to the 33 other patients who remained on their initial CTP treatment and did not require

additional treatment. Head, neck, limb involvement refers to the number of patients that had an LS lesion in that anatomic site. The number of anatomic sites is based upon the divisions used for the LS Cutaneous Activity measure; the body is divided into 19 sites (as described in legend to Table 3).

The p values on the “Race” and “Subtype” rows refers to the significant difference found in the distribution of all of the listed races or subtypes, respectively. Also found significant were frequency of linear scleroderma ($p = 0.0089$), mixed morphea ($p = 0.0305$), and mixed, generalized, and pansclerotic morphea together ($p=0.002$); generalized and pansclerotic morphea together approached significance, $p=0.058$.

ANA: antinuclear antibody; CTP: consensus treatment plan; IQR: interquartile range; LoSDI: Localized Scleroderma Damage Index; LSCAM: localized scleroderma cutaneous activity measure; LSDam: localized scleroderma cutaneous damage measure; mLoSSI: modified Localized Scleroderma Severity Index; no: number; NS: non-significant; PGA-A: Physician global assessment of disease activity; PGA-D: Physician global assessment of disease damage; TF: treatment failure.
