Blastomycotic Multifocal Arthritis and Osteomyelitis in the Urban Setting

To the Editor:

Arthritis due to blastomycosis is uncommon and reports of multiple joint involvement are rare. *Blastomycosis dermatitidis* is endemic in Midwest states around the Great Lakes, the southeast, and the south central United States^{1,2}. Humans acquire this fungus by inhalation of spores from the soil, usually in rural settings³. Infection by blastomycosis is most frequently found in adults aged 20–50 years^{4,5}, with annual incidence reported in up to 100 cases per 100,000 people in specific areas of the United States⁶. In children, cases are infrequent, accounting for 3%–10% of total reported cases, with pneumonia being the most common manifestation⁷. Less

commonly, blastomycosis has been reported to cause arthritis and/or osteomyelitis in children^{8,9}. Blastomycotic arthritis is usually reported as an acute monoarticular arthritis that may be asymptomatic. Juxtaarticular involvement may lead to osteomyelitis. Involvement of multiple joints is very atypical. In children, only 3 reports have documented arthritis as a presenting manifestation of blastomycosis^{8,9,10}. Of these, only 1 report discusses a child presenting with arthritis of more than 1 joint¹⁰.

We describe 7 cases of blastomycotic musculoskeletal involvement including osteomyelitis and arthritis with and without accompanying arthritis in children. Two children had more than 1 affected joint, and the majority of these cases were diagnosed in patients without rural exposure, suggesting a possible migration of blastomycosis into urban areas.

The medical records of 31 children diagnosed with culture-proven

Table 1. Patient demographics, clinical findings, radiographic and laboratory data, treatment, and clinical sequelae for 7 patients, all male. All cases led to full recovery. Normal values based on laboratory standards at Children's Hospital of Wisconsin: leukocyte count 4.0 to 10.5 × 10³/μl; C-reactive protein (CRP) 1 to 1.0 mg/dl; erythrocyte sedimentation rate (ESR) 1–10 mm/h; CNS: central nervous system; MRI: magnetic resonance imaging.

Pt	Age, yrs, race	Chief Complaint	Organ Systems with Physical Findings on Admission	Radiographic Findings	Leukocyte Count, μl	Pathology Site Confirming Blastomycosis	Culture Site Confirming Blastomycosis	Initial ESR, mm/h	Initial CRP, mg/dl
1	13, Hispanic	Weight loss, fever, cough, hemoptysis, joint pain and swelling, scalp soft tissue swelling	Skin, lungs joints, bone	Bone scan-abnormal uptake in left distal clavicle, proximal right humerus, distal right radius, distal diaphysis of left tibia	15,400	Bone	Skin	> 100	4.5
2	15, African American	Cough, fever, joint pain and swelling, pustule on nose	Skin, lung, joint, bone, CNS	MRI left elbow-joint effusion, soft tissue edema, abnormal bone signal in humerus and radius suggestive of osteomyelitis MRI left hip-effusion in left hip joint space Bone scan-abnormal uptake of bilateral elbows, mandible, and distal right fibula	12,600	Not available	Bone	86	8.6
3	12, White	Joint pain	Joint, bone	MRI right elbow-aggressive appearing lesion in distal humerus with peripheral enhancement extending into joint space; diffuse joint effusion	6,400	Bone	Bone	57	3.7
4	7, Hispanic	Joint pain	Bone	MRI left knee-focus of osteomyelitis in distal left femoral metaphysis with focal bony abscess formation, no joint effusion Bone scan-abnormal uptake of distal femoral metaphysis	8,700	Bone	Bone	23	0.3
5	6, Hispanic	Skin lesion	Skin, joint, bone	MRI left femur-abnormal bone signal in left lateral distal femoral epiphysis suggestive of osteomyelitis, including joint effusion of left knee Bone scan-abnormal uptake in left lateral distal femoral epiphysis	4,400	Skin	Not available	Not available	< 0.3
6	17, African American	Weight loss, night sweats, joint pain and swelling, blister on lip	Skin, joint, bone	MRI left lower extremity-bone marrow edema in talar dome, hairline fracture of lateral distal tibia with overlying joint effusion Bone scan-abnormal uptake of left shoulder, left knee, bilateral ankles, right mid distal foot, left glenohumeral joint, right tenth rib, left eighth rib, left costovertebral junction, left distal femoral epiphysis, left femoral condyle	10,900	Bone	Bone	Not available	15.4
7	16, African American	Weight loss, joint pain and swelling, swelling on nose and chest	Skin, joint, bone	Bone scan-abnormal uptake in left parietal bone, left proximal humeral epiphysis, right 4th/5th/9th ribs, left ulna, right iliac, left distal femoral epiphysis, left first metatarsophalangeal joint. left L2 pedicle	9,700	Skin	Skin	79	6.9

blastomycosis at Children's Hospital of Wisconsin between 2000 and 2010 were reviewed retrospectively. Items analyzed included patient demographics, clinical findings, radiographic and laboratory data, treatment, and clinical sequelae (Table 1).

Seven of 31 (22.6%) children diagnosed with *B. dermatitidis* infection had bone and/or joint involvement. Their ages ranged from 6 to 17 years and all were male. Six (85.7%) of the 7 patients were urban dwellers from either metropolitan Milwaukee or Northern Chicago with no known exposure to a rural setting. Six children presented with either bone pain ($n = 1$) and/or arthralgia ($n = 5$). Although 3 of the children reported subjective fevers on history, none of the patients had documented fever at the time of presentation. One patient had asymptomatic bone involvement discovered on imaging. On examination, 5 (71%) had signs of arthritis including joint swelling, erythema, and warmth (3 monoarticular, 1 with 2 joints affected, and 1 with 3 joints affected). All 7 patients had evidence suggestive of osteomyelitis on imaging studies (Figure 1) and in 5 cases, osteomyelitis was histologically confirmed. Of the joints affected, the majority were large joints including elbow, wrist, knee, and hip. Four of 7 had cutaneous lesions and 3 of 7 had pneumonia. Peripheral leukocyte count had a median value of $9.7 \times 10^3/\mu\text{l}$ (range $4.4\text{--}15.4 \times 10^3/\mu\text{l}$). Five patients had blood cultures prior to initiation of therapy; all blood cultures were negative. All 7 patients were immunocompetent and there were no preexisting degenerative lesions at the bone infected sites. Diagnosis of *B. dermatitidis* was by skin biopsy in 2 patients and bone biopsy in 4 patients by the presence of thick-walled, broad-based budding yeast identified through Gomori methenamine silver stain. Granulomatous inflammation was found on all 6 of the biopsy specimens. Bone cultures confirming *B. dermatitidis* were found in 3 patients and skin culture confirming *B. dermatitidis* was found in 2 patients. In Patient 2, diagnosis of *B. dermatitidis* was by bone culture alone. Three patients received intravenous (IV) liposomal amphotericin B 5 mg/kg/day for 2 months followed by oral

itraconazole for 10 months. Patient 1 started IV liposomal amphotericin B 5 mg/kg/day but was switched to IV amphotericin B lipid complex 5 mg/kg/day because of adverse reaction. This patient completed a 2-month course of IV amphotericin B lipid complex followed by 10 months of oral itraconazole. As a result of renal toxicity, Patient 2 received IV liposomal amphotericin B 3 mg/kg/day on 3 days per week to complete a 2-month course followed by 10 months of oral itraconazole. Patient 3 received 2 weeks of IV liposomal amphotericin B 5 mg/kg/day followed by itraconazole 300 mg daily for 12 months. Patient 5 received only oral therapy with itraconazole. No patient had recurrence of infection after treatment.

To our knowledge, all patients in this case series were immunocompetent. However, immunosuppressed patients infected with blastomycosis appear more likely than healthy hosts to develop severe pulmonary infection and disseminated blastomycosis with a high rate of associated mortality¹¹. Cases have been reported in adult patients with AIDS, in solid-organ transplant recipients, in stem cell transplant recipients, in patients with hematologic malignancies, and in patients receiving corticosteroids¹¹. We are unaware of any cases reported in the literature of blastomycosis in immunocompromised children.

The Infectious Diseases Society of America (IDSA) guidelines for the treatment of pulmonary or disseminated blastomycosis in immunocompetent adults include amphotericin B, given as a lipid formulation, 3–5 mg/kg per day, or amphotericin B deoxycholate 0.7–1 mg/kg per day, for 1–2 weeks, followed by step-down itraconazole, 200 mg 3 times per day for 3 days and then twice per day, to complete a total of 12 months of therapy¹¹. Treatment with itraconazole alone for 6–12 months can be considered in cases of mild or localized disease¹¹. Treatment recommendations are similar in immunocompromised patients and children, although there are limited data. However, IDSA guidelines recommend consideration of lifelong suppressive therapy, with oral itraconazole 200 mg per

Figure 1. Patient had evidence suggestive of osteomyelitis.

day, if immunosuppression cannot be reversed and in patients who experience relapse despite appropriate therapy¹¹.

All our patients received a 12-month course of therapy with complete resolution of symptoms and no recurrence; however, only Patient 3 received a course consistent with the IDSA recommendations. The majority of patients in this case series received a much longer course of either liposomal amphotericin B or amphotericin B lipid complex. On review of the literature, the majority of disseminated cases in children (including bone/joint involvement) received parenteral liposomal amphotericin B at smaller doses of 10 to 35 mg/kg total followed by a 2–6 month course of itraconazole or ketoconazole. However, there have been reports of cases of disease recurrence in children with pulmonary blastomycosis who received < 30 mg/kg parenteral antifungal therapy⁹. Based on literature review and our own case series, the IDSA guidelines regarding dose and length of parenteral antifungal therapy in pulmonary or disseminated blastomycosis are appropriate. However, it is reasonable to consider shortening the subsequent course of itraconazole to 6 months. Patients with only monoarticular joint involvement can be considered as having only mild to moderate disease and an oral course of itraconazole for 6–12 months can be considered appropriate therapy. None of our patients or patients reviewed in the literature were immunocompromised; thus we cannot comment on the IDSA guidelines regarding treatment of blastomycosis in this population.

Blastomycosis usually manifests as a respiratory illness in children but can present as an isolated osteomyelitis or arthritis. This disease should be considered in the differential diagnosis of septic arthritis or osteomyelitis, especially in endemic areas. Our cases suggest that children infected with *B. dermatitidis* should be evaluated for bone and joint involvement. *B. dermatitidis* infections of the bone and joint respond well to appropriate antifungal therapy, but can result in poor outcomes if not promptly and adequately treated, including joint destruction and even death^{7,10,11,12}. Based on our findings, *B. dermatitidis* appears to be increasing in incidence in the urban setting and should be considered in the differential of septic arthritis or osteomyelitis for both rural and urban locations. To our knowledge, this is the second report of polyarticular joint involvement in children.
