The Journal of Rheumatology is a monthly international serial edited by Earl D. Silverman featuring research articles on clinical subjects from scientists working in rheumatology and related fields.
Chemerin and Cardiovascular Risk in Rheumatoid Arthritis after Interleukin 6 Receptor Blockade

To the Editor:

We read with great interest the recently published manuscript by Dessein, et al1 regarding chemerin concentrations and cardiovascular disease (CVD) risk in patients with rheumatoid arthritis (RA). The authors state in their discussion that “chemerin may contribute to the link between inflammation and increased risk of coronary artery disease among nonobese patients with RA. Indeed, systemic inflammation was strongly associated with chemerin concentrations in our analysis, and suppression of inflammation with adalimumab is linked to reduced chemerin concentrations in RA.”

We would like to add to this statement the findings of our recently published study of anti-interleukin 6 receptor blockade with tocilizumab (TCZ) on chemerin serum levels, as well as its interrelated plasminogen activator inhibitor 1 (PAI-1) reductions, in 19 patients with RA3. We found that TCZ treatment for 6 months resulted in significant reductions in chemerin and PAI-1 levels in an interrelated manner, despite increasing adiposity. Specifically, chemerin and PAI-1 levels decreased significantly from baseline through 3 to 6 months (from 256 ± 79 to 174 ± 12 and 210 ± 85 ng/ml, p = 0.003; from 73 ± 27 to 56 ± 22 and 51 ± 28 pg/ml, p = 0.029, respectively), while the body mass index and waist circumference increased. In a multivariate model, chemerin decrease was significantly and independently associated with PAI-1 decrease at 6 months (standardized \( \beta \) 0.430, \( p = 0.024 \)). Interestingly, insulin resistance and sensitivity indices (HOMA-IR and Quicki Index) did not change in our study3.

Parallel to that, in an unpublished work, we also measured carotid-femoral pulse wave velocity (PWV) at baseline and at the completion of the 6-month TCZ treatment. Carotid-femoral PWV is considered the simplest, least invasive, strongest, and most reproducible method to determine arterial stiffness, an indicator of arterial atherosclerosis. In a small sample of 10 patients, we found that carotid-femoral PWV decreased significantly (from 8.25 ± 1.38 to 6.96 ± 0.97 m/s, \( p = 0.001 \)) and that chemerin decrease was significantly correlated to carotid-femoral PWV decrease (\( r = 0.837, p = 0.003 \)), further suggesting that chemerin-mediated interactions are involved in the atherosclerotic process in these patients.

We concur with Dessein, et al that, although very indicative, it cannot yet be proven from the data available in the literature that chemerin concentrations on cardiovascular risk stratification in RA. More importantly, from the clinical standpoint, the role of the various modalities of RA treatment on CVD risk, although promising, needs further investigation. The works by Dessein, et al and ourselves contribute to the current knowledge.
