

Evaluation of Germinal Center-like Structures and B Cell Clonality in Patients with Primary Sjögren Syndrome with and without Lymphoma

Svein Joar Johnsen, Ellen Berget, Malin Viktoria Jonsson, Lars Helgeland, Roald Omdal, and Roland Jonsson

ABSTRACT. Objective. Germinal center (GC)-like structures have previously been observed in minor salivary glands (MSG) of patients with primary Sjögren syndrome (pSS). The aim of our study was to explore the prevalence and features of GC-like structures and B cell clonality in patients with pSS with and without lymphoma.

Methods. Based on a nationwide survey in Norway, we included 21 patients with pSS and with a concomitant lymphoma from whom MSG and/or lymphoma biopsies were available. Tonsil biopsies and MSG from 28 patients with pSS without lymphoma were used as controls. The presence of GC-like structures was investigated with H&E staining and double staining for CD21/IgD and CD38/IgD. B cell clonality in MSG and tumors were investigated with analysis of immunoglobulin gene rearrangements.

Results. H&E labeling of MSG revealed GC-like structures in 17/40 (43%) of the patients: 4/12 (33%) with and 13/28 (46%) without lymphoma. Staining for CD21/CD38/IgD demonstrated CD21+ networks in 27/40 (68%) of the patients. CD21+/CD38- infiltrates were seen in 25/40 (63%) of the patients, and 16 of these were IgD+ within the infiltrate. Five percent (2/40) of the patients presented with CD21+/CD38+ infiltrates resembling tonsillar GC. Monoclonal B cell infiltration in MSG was present in 5/12 patients (42%) with and 5/28 patients (18%) without lymphoma ($p = 0.12$). In 2/10 (20%) of cases where both MSG and lymphoma biopsies were available, identical clonal rearrangements were detected.

Conclusion. GC-like structures seen in H&E-stained MSG may represent various subtypes of CD21+ infiltrates. We were unable to detect a clear association between cellular infiltrates, B cell clonality, and lymphoma development. (J Rheumatol First Release Oct 1 2014; doi:10.3899/jrheum.131527)

Accepted for publication July 24, 2014.

Primary Sjögren syndrome (pSS) is a chronic autoimmune exocrinopathy histopathologically characterized by mononuclear cellular infiltration and destruction, mainly of the salivary and lacrimal glands. In most patients, this leads to reduced saliva and tear production, with subsequent oral and ocular dryness phenomena (xerostomia and keratoconjunctivitis sicca). Extraglandular manifestations such as myalgia, arthralgia, and fatigue are common, and immunological disturbances in terms of hypergammaglobulinemia, rheumatoid factor, and autoantibodies against the ribonucleosides SSA/Ro and SSB/La are frequently encountered¹, and even seem to be present long before symptom onset². The pathogenesis of pSS is largely unknown. Associations to MHC genes and non-MHC genes important for immune, inflammation, and regulatory functions have been demonstrated^{3,4,5}, and an interaction between genetic predisposition and unknown environmental factors are thought to represent the necessary players for the devel-

opment of disease. A strong interferon signature is present in a substantial number of patients with pSS⁶.

The cellular infiltrates in pSS salivary glands reportedly consist of T, B, and plasma cells, macrophages, and follicular dendritic cells⁷, and seem to be stable over time⁸. Ectopic germinal center (GC)-like structures can be observed in H&E-stained minor salivary gland (MSG) sections in 20–30% of patients with pSS⁹. The presence of GC-like structures seems to distinguish a distinct disease phenotype^{10,11,12,13}, and GC formation has recently been suggested as a predictor for lymphoma development¹⁴. Additional staining for the CD21 marker to detect follicular dendritic cell (FDC) networks has been widely applied in evaluation of GC-like structures^{7,12,15,16}, and the CD38 marker has been used to detect GC B cells^{17,18}. Expression of activation-induced cytidine deaminase (AID) has been demonstrated in GC-like structures by immunohistochemical staining and quantitative real-time PCR^{15,16}, suggesting functionality. In addition, the marker CD38 seemed to differentiate AID-expressing versus non-AID-expressing infiltrates¹⁶. GC-like structures are also known as “tertiary lymphoid organs”, and an analog lymphoid organization is seen in target organs of patients with other autoimmune diseases¹⁹. Criteria for the term “tertiary lymphoid organs” have been suggested²⁰, but no consensus has been reached about the term “GC-like structures” in rheumatology. In addition, mechanisms leading to formation of GC-like structures or their role in autoimmune disease pathogenesis are not entirely clear^{9,15,16,21,22}.

There is a 6.5 to 15.6-fold increased risk for non-Hodgkin lymphomas in pSS^{23,24,25}, the most common lymphoma (MZL) subtype being extranodal marginal zone lymphoma of the mucosa-associated lymphoid tissue (MALT)²⁶. MALT lymphomas are distinct neoplasms that arise extranodally in the setting of chronic inflammatory disorders²⁷. The malignant cells originate from B cells in the marginal zone of GC²⁸. The current understanding is that the development of MALT lymphoma is antigen driven, and that the nuclear factor- κ B (NF- κ B) pathway seems to play a central role in this concept²⁹. Four specific chromosomal translocations have been described in MALT lymphomas, which all lead to aberrant NF- κ B activation²⁸. Primary SS lymphomas and salivary gland MALT lymphomas, in general, rarely present with any of these translocations³⁰, but seem to harbor various genomic alterations that could interact with other genes modulating the NF- κ B pathway^{31,32}. Recently, an association between antibody-positive pSS and genes in the NF- κ B pathway was demonstrated³³.

The aim of our study was to evaluate the possible difference between patients with pSS with and without lymphoma regarding B cell clonality, and prevalence and features of GC-like structures.

MATERIALS AND METHODS

Patients and controls. Based on data from the Cancer Registry of Norway³⁴, we performed a retrospective nationwide search for patients with a combination of pSS and lymphoma. For inclusion, patients had to fulfill the American-European Consensus Criteria for pSS³⁵, and at least 1 formalin-fixed and paraffin-embedded tissue block of either a lymphoma or a MSG biopsy had to be available. Because patients with pSS sometimes have a long period with vague and weak symptoms delaying the diagnosis, patients who developed lymphoma prior to or simultaneously with the establishment of the pSS diagnosis were included in our study.

We identified 33 patients with pSS who had been diagnosed with a lymphoma between January 1, 1986, and December 31, 2012. Of these, 21 patients had tissue blocks available for further study: 10 patients with both lymphoma and MSG tissue blocks, 9 patients with lymphoma tissue blocks, and 2 patients with MSG tissue blocks only. Two patients had tissue blocks from sequential lymphomas, leaving 21 lymphomas and 12 MSG tissue blocks available for study. Because of changing nomenclature and criteria over time, histopathological sections were reexamined and reclassified according to standard protocols for present lymphoma classification (Supplementary Table 1, available from authors on request).

Twenty-eight MSG biopsies from patients with pSS without lymphoma, matched for sex and age at the time of the biopsy, were provided from the biobank at Stavanger University Hospital for controls. To evaluate the staining pattern in secondary lymphoid tissue, tonsil tissue sections from subjects undergoing tonsillectomy because of other medical indications but without known malignancy or autoimmune diseases were provided from the department of Otolaryngology, Head and Neck Surgery, Haukeland University Hospital, Bergen.

Formalin-fixed, paraffin-embedded tissue sections. Lymphoma, MSG, and tonsil tissue blocks were cut in 3- μ m slices using a microtome (Leica Instruments GmbH) and placed onto SuperFrost Plus microscope slides (Menzel GmbH and Co.).

Immunohistochemical staining of lymphomas. Following de-paraffinization, rehydration, and heat-induced epitope retrieval, tissue sections were incubated with primary antibodies [CD3, CD20, CD21, CD79a, Ki-67, BCL2, BCL6, λ , and κ (Dako); CD2, CD5, CD10, CD23, and PAX5 (Novocastra, Leica Biosystems); CD138 and CyclinD1 (NeoMarkers); Foxp3 (BD Biosciences); EBER (Roche); BOB1a and OCT2 (Santa Cruz Biotech)] using the Dako EnVision Autostainer system (Dako). Staining with CD3, CD20, and Ki-67 was performed with the Ventana Medical Systems Stainer, and EBER staining with the Ventana's OptiView DAB IHC Detection Kit (Ventana).

Double-labeling of MSG sections with CD21/IgD and CD38/IgD. Immunohistochemical double staining of consecutive MSG and tonsil sections was performed with CD21/IgD and CD38/IgD using the Dako EnVision Doublestain System as described by the manufacturer. All sections were de-paraffinized and rehydrated overnight, followed by heat-induced epitope retrieval (Dako PT-link) and incubation with endogenous enzyme block for 10 min. Sections were then incubated with the first primary antibody, monoclonal mouse anti-human CD21 (Dako) diluted 1:15 or CD38 (Novocastra) diluted 1:50 for 60 min, before incubation with the second primary antibody, polyclonal rabbit anti-human IgD (Dako) diluted 1:2 for 60 min. The sections were then incubated for 30 min with anti-rabbit/mouse polymer AP link (Dako), Liquid Permanent Red 10 μ l/ml buffer for 10 min, and then washed with water for 5 min. After counterstaining with hematoxylin for 10 min and a final wash in water, the sections were dehydrated through ethanol and xylene for 5 min and mounted with Eukitt.

Evaluation of staining patterns. Sections were evaluated using a light microscope. All the H&E-stained MSG were assessed for GC-like structures, defined as a well-circumscribed chronic cellular infiltration consisting of \geq 50 mononuclear cells with features indicating lymphoid organization and morphology resembling a dark zone, and a light zone within otherwise normal salivary gland epithelium^{13,14}.

Table 1. Baseline characteristics for patients with pSS with and without lymphoma.

Characteristics	Patients without Lymphoma, n = 28	Patients with Lymphoma, n = 21	All Patients, n = 49	p
Age, yrs, at pSS diagnosis, median (range)	52 (34–85)	51 (29–78)	51 (29–85)	NS
Disease duration, yrs, median (range)	10 (5–23)	13 (2–36)	10 (2–36)	NS
Age lymphoma diagnosis, yrs, median (range)	—	53 (31–78)	—	—
Female sex, n (%)	23 (82)	19 (91)	42 (86)	NS
Anti-SSA and/or anti-SSB antibodies (%)	25/28 (89)	17/21 (81)	42/49 (86)	NS
Symptoms of ocular dryness (%)	20/27 (74)	21/21 (100)	41/48 (85)	0.01
Symptoms of oral dryness (%)	25/27 (93)	20/21 (95)	45/48 (94)	NS
Reduced tear flow* (%)	21/27 (78)	11/12 (92)	32/39 (82)	NS
Reduced unstimulated salivary flow (%)	19/26 (73)	8/11 (73)	27/37 (73)	NS

*Tested with Schirmer test (< 5 mm/5 min). Categorical variables were analyzed by Fisher's exact test and continuous variables by the Mann-Whitney U test. pSS: primary Sjögren syndrome; NS: not significant.

The tonsil tissue sections were used as a positive control for the double-staining. The CD21/IgD-stained sections were assessed for a CD21+ network-like staining pattern in the presence of a surrounding IgD+ mantle zone, and the CD38/IgD-stained sections for a localized cellular aggregate containing CD38+ B cells and surrounded by an IgD+ mantle zone. Other IgD-staining patterns, such as scattered positive cells within infiltrates and single-positive cells in small interstitial cell clusters related to glandular epithelial cells, were also noted. An overall evaluation was performed by assessing the double-stainings, and to categorize the staining patterns into 3 groups termed nonspecific (CD21–/CD38–/IgD–), focal cellular infiltrates (CD21+/CD38– networks), or partially characterized GC (CD21+/CD38+ networks), similar to secondary lymphoid tissue from tonsillar tissue sections. All lymphoma sections were examined by LH and SJJ. MSG sections were blindly read by MVJ and SJJ, reaching agreement in 116/120 cases. The remaining 4 cases were discussed with a senior author (RJ) and a final decision was reached.

DNA extraction. Three 10- μ m sections were cut from all available MSG and lymphoma biopsies, and the sections de-paraffinized with xylene, dehydrated in 100% ethanol, and set for overnight proteinase K (20 mg/ml) digestion. DNA was prepared manually using the E.N.Z.A Tissue DNA kit according to the manufacturer's instructions (Omega Bio-Tek).

PCR analysis of B cell clonality. The multiplex PCR kit (catalogue no. 206143, Qiagen) with HotStarTaq DNA polymerase was used for the clonality analysis. Five BIOMED-2 primer sets including immunoglobulin heavy chain VH-JH (Fr1, Fr2, and Fr3), immunoglobulin light chain VK-JK, and κ deleting element were run separately³⁶. We used a modified BIOMED-2 protocol, mixing 2.5 μ l DNA template, 2.5 μ l primer mix (2 μ m of each primer), 12.5 μ l Multiplex buffer, and 7.5 μ l water to a final reaction volume of 25 μ l³⁷. All samples were run with undiluted and 5-fold diluted template DNA, and monoclonal, polyclonal, and nontemplate controls were included in all runs. The PCR conditions included an initial activation step (95°C, 15 min), followed by 38 cycles consisting of denaturation (95°C, 45 s), annealing of primers (60°C, 90 s), and extension (72°C, 90 s), before a final extension step (70°C, 10 min) followed by cooling to 4°C³⁷.

Assessment of B cell clonality. Fragment analyses of the PCR products were performed using Applied Biosystems PRISM 3100 capillary sequencer (Applied Biosystems). Identification of 1 or 2 peaks within expected range consistent after dilution was interpreted as clonal. All samples were assessed for clonality by LH and EB, and a consensus was established.

Statistical analyses. Non-parametric statistics were used, and groups were

compared with the Mann-Whitney U test for continuous variables, Fisher's exact test for categorical variables, and the Freeman-Halton extension for a 4×2 contingency table.

Ethics and approval. The Regional Committee for Medical and Health Research Ethics approved our study (REK Vest 2009-250/17, 2009-250/18).

RESULTS

Patients. The baseline characteristics of the patients with pSS with (n = 21) and without (n = 28) lymphoma are shown in Table 1. Controls were selected to match the age and sex of the patients with lymphoma, hence the groups were similar regarding age, disease duration, and sex. However, the patients with lymphoma were more likely to have a positive MSG biopsy and had higher focus score. The median time between pSS diagnosis and lymphoma development was 15 months, and the range was from 240 months before the pSS diagnosis to 224 months after the pSS diagnosis. Four patients (19%) were diagnosed with lymphoma before pSS, 5 patients (24%) had both conditions diagnosed at the same time (± 6 mos), and 12 (57%) were diagnosed with lymphoma after pSS.

Reclassification of the lymphomas showed that the majority of patients (71%) had an MZL (Table 2). One patient had a nodal MZL, and all the remaining were extranodal MZL (67%). The majority (62%) of the MZL was of the MALT subtype and was located in the salivary glands (52%). Details of lymphoma subtypes and localization are given in Table 2. Finally, 2 of the lymphoma blocks (1 bone marrow biopsy and 1 pulmonary fine needle aspiration) did not contain enough material for a full reclassification.

Immunohistochemical staining. In the H&E-stained MSG sections, GC-like structures (Figure 1A–B) were seen in 17/40 (43%) of the patients: 4/12 (33%) of the patients with lymphoma and 13/28 (46%) of the patients without lymphoma, respectively (Figure 2A). There was no signifi-

Table 2. Overview of lymphoma types, subtypes, localization, and detection of immunoglobulin gene rearrangements.

Type	Subtype	Localization	Total, n (%), n = 21	Monoclonality (%)	
MZL			15 (71)	12/15 (80)

*One patient had 2 lymphoma subtypes in the bone marrow. MZL: marginal zone lymphoma; MALT: mucosa-associated lymphoid tissue.

cant difference in frequency of GC-like structures in the H&E-stained sections between the groups ($p = 0.51$).

The double-staining with CD21/IgD demonstrated CD21+ networks in 27/40 of the patients (68%), and both markers were negative in the remaining 13/40 patients (33%). CD21+ networks were detected in 16/17 of the patients (94%) with GC-like structures seen in the H&E-staining sections. Three different IgD-staining patterns were seen in the CD21+ tissue sections: 16/40 of the patients (40%) presented with colocalization of IgD+ cells and CD21+ networks, 10/40 (25%) were completely IgD-, and in 1 patient the CD21+ networks resided within surrounding IgD+ mantle zones. CD21+ networks were seen in 7/12 of patients with lymphoma (58%) and 20/28 of patients without lymphoma (71%; Figure 2B), but this difference was not significant ($p = 0.48$).

The CD38/IgD double-staining showed CD38- infiltrates in 38/40 (95%) of the patients. A cluster of CD38+ B cells with GC-like appearance was seen in only 2/40 of the patients (5%), and 1 of these revealed an IgD+ mantle zone. Both patients with a CD38+ infiltrate were in the group without lymphoma ($p = 0.08$).

An overall evaluation of the double-labeling demonstrated CD21+ networks in 27/40 (68%) of the patients; CD21+/CD38+ partially characterized GC were found in 2/40 of the patients (5%; Figure 1E-F); CD21+/CD38- focal cellular infiltrates (Figure 1G-H) were seen in 25/40 of the patients (63%); and in 16/40 of the patients (40%), the CD21+ infiltrates were IgD+. The remaining 13/40 of the patients (33%) presented with nonspecific staining pattern within cellular infiltrates (CD21-/CD38-/IgD-). The difference in the distribution of subtypes of infiltrates was not significant between the groups ($p = 0.40$; Figure 2C), but there was a highly significant association between GC-like structures in the H&E-stained sections and CD21+ FDC networks in the double-stained sections ($p = 0.002$; Figure 2D).

Detection of B cell clonality. The PCR analyses revealed monoclonal B cell infiltration more frequently in MSG of patients with pSS with lymphoma 5/12 (42%) compared to patients with pSS without lymphoma 5/28 (18%), but this difference was not statistically significant ($p = 0.12$; Figure 3). There was no association between presence of monoclonal B cell infiltration and GC-like structures or CD21+ networks in MSG in any of the patient groups.

Monoclonal B cell infiltration was detected in 15/21 of all the lymphomas (71%), and in 11/13 of the lymphomas (87%) located in the salivary glands. In the patients with a history of a lymphoma, there was no significant difference in the frequency of monoclonal B cell infiltration between the lymphoid tumors and the MSG ($p = 0.14$). In 10 patients where both lymphoma and MSG tissue were available, monoclonal B cell infiltration was detected in 3 of the patients (30%), and the PCR analysis showed identical sized clonal rearrangements suggestive of identical B cell clones in 2 of these (20%). Both of these lymphomas were MZL: 1 salivary gland MALT, and 1 nodal MZL.

DISCUSSION

In the investigated cohort of patients with pSS with and without lymphoma, GC-like structures were observed at similar levels in the H&E-stained MSG tissue sections, but the CD21/CD38/IgD labeling showed that the majority of the cellular infiltrates had other immunohistochemical characteristics as compared to tonsillar GC. There was a strong association between the observation of GC-like structures in H&E-stained sections and CD21+ networks in the double-stained sections. As previously described, the CD21+ infiltrates seem to encompass various different staining patterns⁷ that cannot be identified in the H&E staining. GC-like structures or CD21+ infiltrates were not seen more frequently in the group with lymphoma, but were frequent in both groups. We found a trend toward an

Figure 1. Minor salivary gland H&E staining and immunohistochemical double-staining with CD21/IgD and CD38/IgD. H&E staining demonstrated GC-like structures (A, B), but the H&E staining did not discriminate between various phenotypic subtypes of infiltrates. In tonsil sections, GC stained positive for CD21 (C) and CD38 (D), and the surrounding mantle zone stained positive for IgD. Similar staining patterns were also seen in a minority of the MSG, with CD21+ (E) and CD38+ (F) GC-like structures surrounded by an IgD+ mantle zone. In the majority of patients, the double-staining showed a different staining pattern, with CD21+ (G) and CD38- (H) lymphocytic infiltrations without a surrounding IgD+ mantle zone. In many of the patients, the CD21+ infiltrates also stained IgD+ within the infiltrate (H). Inset bar indicates 100 μ m. GC: germinal centers; MSG: minor salivary glands.

Figure 2. (A) H&E staining demonstrated no significant difference in distribution of GC-like structures in MSG of patients with and without lymphoma ($p = 0.51$). (B) Double-staining with CD21 and IgD showed that the majority of patients had CD21+ FDC networks, but regarding the presence of CD21+ networks, there was no significant difference between the patients with and without lymphoma ($p = 0.48$). (C) The majority of patients presented CD21+/CD38- focal cellular infiltrates, and most of these stained IgD+ within the infiltrate. Only 2 patients presented with CD21+/CD38+ infiltrates, similar to secondary lymphoid tissue GC. (D) A significant association was seen between GC-like structures observed in H&E-stained sections and CD21+ networks in the double-stained section ($p = 0.002$). The comparison was performed using Fisher's exact test. GC: germinal center; FDC: follicular dendritic cell; MSG: minor salivary glands.

increased frequency of monoclonal B cellular infiltration in the group of patients with lymphoma. We also detected identical B cell clones in tissue sections from both MSG and lymphoid tumors in 2 patients with MALT lymphoma; this finding supports the hypothesis that development of lymphoproliferative disease in pSS is antigen-driven³⁸.

Inflammatory cellular infiltrates and infiltrates with morphological features similar to lymphoid GC have previ-

ously been observed in the MSG tissue in patients with pSS and extensively studied^{7,9,10,11,12,13,14,15,16,39}. Based on expression of AID and immunohistochemical staining, a further dichotomization between real GC and cellular aggregates has been suggested¹⁶. In our study, with a few selected markers, only a minority of the MSG cellular infiltrations seem to contain all the selected phenotypic and structural elements from a secondary lymphoid GC. The majority of

Immunoglobulin gene rearrangements analyses

Figure 3. Immunoglobulin gene rearrangements analyses of labial MSG and lymphomas showed that monoclonal B cell infiltrations in MSG were seen more frequently in the group with lymphoma compared to the group without lymphoma, but this difference was not significant ($p = 0.12$). In patients with lymphoma, no significant differences in frequency of monoclonal B cell infiltration were seen between lymphoma tumors and MSG ($p = 0.14$). The comparison between the groups was performed using Fisher's exact test. MSG: minor salivary glands.

the focal mononuclear infiltrates contained CD21+ networks, colocalized within a cluster of IgD+ cells, but lacking an IgD+ mantle zone. These focal cellular infiltrates seem similar to the non-AID-expressing cellular infiltrates previously described^{16,40}. There was a strong association between GC-like structures and CD21+ networks, but the CD21+ infiltrates seem to include several staining patterns. This finding implies that the GC-like structures seen in H&E-stained MSG sections, in fact, could represent at least 3 different phenotypes of infiltrates. Because of the study design, clinical implications or relevance of such a subclassification was not investigated.

The majority of the lymphomas (62%) were located in the salivary glands, and monoclonal B cells were observed in 85% of lymphomas located in salivary glands. In some lymphomas, no monoclonal B cell infiltration was detected, and possible explanations for this could be DNA degradation, DNA taken from the periphery or outside the actual tumor, or mutations that led to a lack of sufficient primer coverage. Monoclonal B cell infiltrations have previously been described in MSG of patients with pSS without lymphoma^{41,42}, and are not considered a valuable predictor for lymphoma development⁴³. Our study showed a trend

toward a higher frequency of monoclonal B cell infiltration in MSG of patients with a history of lymphoma. In line with previous findings, identical B cell clones were also detected in the MSG and lymphoma tissue biopsies in 20% of the patients where both tissues were available^{44,45}. This result supports the idea that the lymphoma development is antigen-driven³⁸, but the antigen driving the clonal selection remains unknown. It has been shown that malignant B cells in pSS express rheumatoid factor specificity, but without binding self-antigens⁴⁶. A recent study suggested an association between an active Epstein-Barr virus infection and formation of GC-like structures in MSG of patients with pSS⁴⁷, in accordance with current opinion that chronic immune stimulation is a possible mechanism for pSS lymphoma development²⁷.

A limitation of our study is the sample size. Based on the prevalence of lymphoma in pSS in Norway, we expected to identify 35 patients with pSS and lymphoma²⁴; hence the numbers of patients enrolled were lower than expected. Also, the distribution of the IgD staining was nonhomogeneous across the sections in 9/40 of the patients (23%). Some MSG biopsies had been performed after the lymphoma was diagnosed. Although all patients were naive for B cell depletion therapy when the biopsy was performed, 2 more patients received chemotherapy (cyclophosphamide, doxorubicin, vincristine, prednisone) before the MSG biopsy was performed, and that might have influenced our results. It is still unclear whether GC formation is characterized best by the functional or morphological features²⁰. Our study evaluates only the morphology of the cellular infiltrates, and AID expression analysis might have provided additional information.

Our study indicates that the GC-like structures seen in H&E staining seem to be represented by various subtypes of CD21+ staining patterns. Although we were unable to reveal an association among the presence of GC-like structures, monoclonal B cell infiltration, and lymphoma development, the detection of identical B cell clones in MSG and lymphoma suggest an association between antigen-mediated clonal selection and lymphoma development.
