

Association of Serum Soluble CD163 with Polymyositis and Dermatomyositis, Especially in Anti-MDA5 Antibody-positive Cases

Hidenaga Kawasumi, Yasuhiro Katsumata, Akira Nishino, Shinya Hirahara, Yasushi Kawaguchi, Masataka Kuwana, and Hisashi Yamanaka

ABSTRACT. Objective. We elucidated the association of serum soluble CD163 (sCD163) with rapidly progressive interstitial lung disease (RP-ILD), autoantibody profiles, and serum ferritin in patients with polymyositis (PM), classic dermatomyositis (DM), and clinical amyopathic dermatomyositis (CADM).

Methods. Serum sCD163 levels were retrospectively measured by ELISA in patients with PM, classic DM, and CADM, as well as in healthy controls (HC). Repeat sera samples were obtained posttreatment from available patients. The associations between serum sCD163 levels and clinical information were analyzed.

Results. Serum sCD163 levels in patients with PM/classic DM/CADM were significantly higher than those in HC ($n = 72, 56, 34$, and 68 , respectively; $p < 0.001$ for all comparisons). No significant difference was observed between serum sCD163 levels in patients with and without ILD ($p = 0.16$) or between those with RP-ILD and chronic ILD ($p = 0.21$). Serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies ($n = 27$) than in those without ($p = 0.001$). Serum sCD163 levels were weakly correlated with serum ferritin levels in the patients with PM, classic DM, and CADM ($r = 0.21$). Serum sCD163 levels decreased significantly following treatment in all patient groups ($p = 0.003$).

Conclusion. The present results suggest an association of serum sCD163 with PM, classic DM, and CADM, especially in anti-MDA5 antibody-positive cases. However, serum sCD163 levels were not specifically associated with ILD or RP-ILD. (J Rheumatol First Release April 15 2018; doi:10.3899/jrheum.170997)

macrophages, dendritic cells, B cells, and plasma cells in muscle tissue^{1,2}. In addition, a subset of patients with DM have cutaneous lesions in the absence of muscle weakness, known as clinically amyopathic dermatomyositis (CADM)². PM/DM is often complicated by interstitial lung disease (ILD)³. Although therapeutic strategies have improved the clinical courses of patients with PM/DM^{4,5,6}, ILD is a major prognostic factor for PM/DM⁷. In particular, rapidly progressive (RP)-ILD, mostly complicated with CADM and/or antineoplastic differentiation-associated gene 5 (anti-MDA5) antibodies, is a life-threatening complication⁸.

Predicting disease progression, the prognosis, and treatment response are important when making treatment decisions, given the heterogeneity of the clinical course of PM/DM-associated ILD⁹. We have reported previously that high levels of serum ferritin, an iron-binding protein, are associated with the severity and prognosis of ILD with PM/classic DM/CADM, particularly in a patient with anti-MDA5 antibodies^{8,10,11}. In addition, we demonstrated that accumulated macrophages synthesize ferritin in the lung and bone marrow of a patient with RP-ILD associated with

DM¹². We also reported that proinflammatory cytokines, such as interleukin (IL)-6 and IL-18, are involved in the pathogenesis of RP-ILD^{12,13,14}. A series of our previous studies^{12,13,14} led us to conjecture that macrophages are extremely activated in patients with RP-ILD, and that the high levels of serum ferritin are probably produced through activation of macrophages along with a flood of cytokines, similar to patients with macrophage activation syndrome¹⁵. Although the mechanism of hyperferritinemia in CADM-related and/or anti-MDA5 antibody-related RP-ILD remains elusive, we hypothesized that the high level of serum ferritin might be secreted by systemically activated macrophages. Although the detailed secretory pathway of serum ferritin is not completely understood, macrophages, hepatocytes, and Kupffer cells secrete ferritin¹⁵. In addition, macrophages are generally considered to be responsible for the production of cytokines and to be of utmost importance in the production and secretion of serum ferritin in 4 uncommon medical conditions characterized by high levels of ferritin, such as macrophage activation syndrome, adult-onset Still disease, catastrophic antiphospholipid syndrome, and septic shock¹⁵.

CD163 is a glycoprotein expressed by peripheral monocytes and activated macrophages^{16,17}. CD163 is shed from activated macrophages during acute or chronic inflammation and is released into peripheral blood in a soluble form¹⁸. Thus, soluble CD163 (sCD163) in the sera suggests macrophage activation. It has been reported that an increase in serum sCD163 level suggests macrophage activation in some diseases, such as sepsis, lymphoma, and macrophage activation syndrome^{19,20,21}. In addition, a few studies have suggested an association between sCD163 and PM/DM, particularly in patients with PM/DM-associated ILD, but not with autoantibody profiles^{22,23}. However, such an association remains inconclusive because of the statistical methodologies of those studies and the small numbers of cases included. Further, the association between sCD163 and ferritin has scarcely been studied. In our present study, we elucidated the association between serum sCD163 and RP-ILD, autoantibody profiles, and serum ferritin in patients with PM/classic DM/CADM.

MATERIALS AND METHODS

Study subjects and sample collection. Adult patients with PM/classic DM/CADM and healthy controls (HC) were eligible for our present study. Some patients' serum samples used in our present study were collected previously and stored for unspecified medical studies under general consent from 1994 to 2016, and other samples were prospectively collected specifically for our present study at Tokyo Women's Medical University under written informed consent. Sera from healthy subjects were used as the HC. All sera were stored at -80°C before use. PM/classic DM and CADM were diagnosed according to Bohan and Peter's criteria^{24,25}, and Sontheimer's criteria²⁶, respectively. Overlapping patients with other collagen tissue diseases and patients complicated with active infection were excluded to avoid potential confounding. All patients with PM/classic DM/CADM were referred to our hospital because of active disease, and all initial serum

samples were collected before starting or reinforcing immunosuppressive treatment, usually upon admission. Sera were collected again later from available patients at some time after treatment. The intervals between the time of initial evaluation and reevaluation ranged from 289 to 1658 days (median 619 days). The immunosuppressive treatment was determined according to physician preference in each individual, based on clinically available information and without prior knowledge of the serum sCD163 level. Clinical, radiological, and laboratory data were collected retrospectively from the medical records. ILD was defined as the presence of a diffuse parenchymal lung disease, such as reticular opacity, ground-glass opacity, and honeycombing on high-resolution computed tomography (HRCT). RP-ILD was defined as a rapidly progressive ILD within 3 months of the onset of respiratory symptoms, whereas chronic ILD was defined as progressive dyspnea that developed slowly over > 3 months^{8,10}. Response of ILD to treatment was retrospectively judged using Myositis Intention to Treat Activity Index (MITAX)²⁷ by 2 mutually independent rheumatologists (HK and YK). In MITAX, ILD is categorized as worse, the same, or improved when ≥ 2 of the following were fulfilled: (A) dyspnea or cough because of ILD; (B) parenchymal abnormalities on chest radiograph or HRCT and/or ground-glass-shadowing; and/or (C) 10% change in total lung capacity/forced volume vital capacity (VC) or 15% change in DLCO by pulmonary function tests. This study was approved by the Ethical Committee of Tokyo Women's Medical University (registration nos. 3600 and 3733), and the Declaration of Helsinki was followed throughout the study.

Assessment of serum myositis-specific autoantibodies. Myositis-specific autoantibodies (MSA) were assessed as described previously²⁸. Briefly, anti-aminoacyl-tRNA synthetase (anti-ARS) antibodies (anti-Jo1, anti-EJ, anti-OJ, anti-PL7, anti-PL12, and anti-KS), as well as anti-signal recognition particle antibodies, were identified by RNA immunoprecipitation assays using unlabeled HeLa cell extracts. Anti-MDA5 antibodies were measured by ELISA. Anti-Mi2, antinuclear matrix protein 2, and antitranscriptional intermediary factor 1-γ antibodies were identified by protein immunoprecipitation assay using 35S-labeled HeLa cell extracts.

Measurement of serum sCD163 levels. The levels of serum sCD163 were determined by commercial solid phase sandwich ELISA kits, using 96-well microplates precoated with a monoclonal antibody specific to human CD163 as the capture antibody, a monoclonal antibody specific for human CD163 conjugated to horseradish peroxidase as the detection antibody, 3,3',5,5'-tetramethylbenzidine substrate, and recombinant human CD163 as the standard (Human CD163 Quantikine ELISA Kit; R&D Systems), according to the manufacturer's protocol. The absorbance was measured in a microtiter plate reader (Bio-Rad, Hercules) at a wavelength of 450 nm. Duplicate readings were averaged for each standard, control, and sample, and the average zero standard optical density was subtracted. The best-fit lines were drawn through the standard points using the plot software. The detection range of sCD163 was 1.6 ng/ml–100 ng/ml when samples were not diluted. Samples were diluted 10- or 50-fold. The product datasheet of this ELISA kit gave the mean and range of serum sCD163 levels from apparently healthy volunteers (n = 36) as 472 ng/ml and 88 to 902 ng/ml, respectively.

Statistical analyses. Two-group comparisons were analyzed using Fisher's exact test for categorical variables and Welch t test for continuous variables. Multiple comparisons for continuous variables were performed using the Tukey–Kramer method. Correlations were evaluated by Pearson correlation coefficient analysis. The difference between the levels of sCD163 before and after treatment was evaluated by the paired t test. P values < 0.05 were considered significant, and all tests were 2-tailed. All statistical analyses were performed using JMP Pro statistical software (version 12.0; SAS Institute) and EZR (Saitama Medical Center, Jichi Medical University, Saitama, Japan)²⁹.

RESULTS

Clinical characteristics of the patients with PM, classic DM, and CADM. Sera were available from 72, 56, and 34 patients with PM, classic DM, and CADM, respectively, and 68 HC

and were used in our present study. The median age of these patients was 54 years (range 22–81 yrs). The median disease duration of PM/classic DM/CADM was 7.4 months (range 0.7–233 mos). The patients and HC were all Japanese. Other clinical characteristics of the patients are summarized in Table 1. Consistent with our previous reports, serum levels of ferritin were significantly higher in patients with RP-ILD than in those with chronic ILD ($p = 0.04$).

Serum sCD163 levels in HC. The number of women and men in the HC were 47 and 21, respectively. The mean age of the healthy controls was 34 years old. There was no significant difference in the sex ratio between the patients with PM/classic DM/CADM and HC, whereas the patients were older than the HC ($p = 0.32$ and < 0.001 , respectively). Among the HC, there was no significant association between serum sCD163 levels and sex ($p = 0.55$), and there was no significant correlation between serum sCD163 levels and age ($r = 0.15$, $p = 0.21$).

Serum sCD163 levels in patients with PM, classic DM, and CADM. As shown in Figure 1, mean sCD163 levels in patients with PM, classic DM, and CADM, as well as the HC, were 992, 867, 1061, and 506 ng/ml, respectively. Serum sCD163 levels in patients with PM, classic DM, and CADM were significantly higher than those in HC ($p < 0.001$ for all comparisons). However, no significant difference was observed between serum levels of sCD163 in patients with PM, classic DM, and CADM. In addition, no correlation was detected between serum sCD163 levels and serum creatine kinase levels or manual muscle testing scores ($r = 0.15$ and -0.08 , respectively), whereas serum levels of sCD163 were weakly correlated with serum aldolase levels in the patients

with PM/classic DM/CADM ($r = 0.25$). No significant difference in serum sCD163 levels was observed between patients with or without cutaneous ulcers and anti-Ro/SS-A antibodies ($p = 0.98$ and 0.09 , respectively). Malignancies had been diagnosed in 9 patients within 3 years prior to the diagnoses of PM/classic DM/CADM, whereas malignancies never developed in any patients within 3 years after the diagnoses. There was no significant difference in the serum sCD163 levels between patients with and without malignancies ($p = 0.88$). There was no significant correlation between serum sCD163 levels and age ($r = 0.04$, $p = 0.65$).

Associations between serum sCD163 levels and ILD. As shown in Figure 2A, no significant difference was observed between serum sCD163 levels in patients with and without ILD in the patients with PM/classic DM/CADM ($p = 0.16$). No significant difference was observed between serum sCD163 levels, even when the patients with ILD were classified into RP-ILD ($n = 36$) and chronic ILD groups ($n = 89$, $p = 0.21$; Figure 2B). There were no significant correlations between serum sCD163 levels and %VC or %DLCO ($r = -0.11$ and 0.02 , $p = 0.23$ and 0.85 , respectively). Additionally, there was no significant difference in the baseline serum sCD163 levels between patients whose ILD deteriorated later, and those whose ILD was ameliorated later or remained unchanged ($p = 0.71$). The baseline serum sCD163 levels in the patients who died were not significantly different from the patients who were alive ($p = 0.32$). By contrast, and consistent with our previous reports^{8,10,11,12,13,14}, baseline serum ferritin levels in patients whose ILD deteriorated were significantly higher than those in patients whose ILD was ameliorated or remained unchanged ($p < 0.001$).

Associations between serum sCD163 levels and myositis-specific autoantibodies. Mean serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies ($n = 27$; 1194 ng/ml) than in those without (917 ng/ml; $p = 0.001$) among the patients with PM/classic DM/CADM. As shown in Figure 3, when the patients without anti-MDA5 antibodies were further categorized into those with anti-ARS antibodies ($n = 55$) and other MSA ($n = 31$), and the remaining patients (i.e., those without any known MSA; $n = 49$), their mean serum sCD163 levels were 966 ng/ml, 747 ng/ml, and 969 ng/ml, respectively. By multiple comparison analyses, serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies than in those with other MSA (i.e., non-MDA5/ARS; $p < 0.001$). Although serum sCD163 levels in the patients with anti-MDA5 tended to be higher than those in patients with anti-ARS and patients without any known MSA, they did not reach statistical significance ($p = 0.10$ and 0.12 , respectively).

Correlations between serum levels of sCD163 and ferritin. As shown in Figure 4A, serum sCD163 levels were weakly

correlated with serum ferritin levels in the patients with PM/classic DM/CADM ($r = 0.21$, 95% CI 0.05–0.36). Serum sCD163 and ferritin levels were moderately correlated in patients with CADM ($r = 0.49$, 95% CI 0.17–0.71; Figure 4B). No significant correlation was detected between serum levels of sCD163 and ferritin in patients with RP-ILD ($r = 0.10$, Figure 4C). In addition, no significant correlation was observed between serum levels of sCD163 and ferritin in anti-MDA5 antibody-positive patients ($r = 0.04$).

Serum sCD163 levels before and after treatment in patients with PM, classic DM, and CADM. Repeat sera samples were available from 44 patients with PM/classic DM/CADM. As shown in Figure 5, retesting showed that serum sCD163 levels decreased significantly following treatment (median decrease –26%, range –67% to 140%, $p = 0.003$). Notably, disease activity of ILD persisted or deteriorated in 7 of the 12 patients (60%) whose serum sCD163 levels increased after immunosuppressive treatment.

DISCUSSION

The major findings of our present study are the following: (1) serum sCD163 was associated with PM/classic DM/CADM; (2) serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies than in the

remaining patients; (3) serum sCD163 levels were not specifically associated with ILD or RP-ILD; and (4) serum sCD163 levels were only weakly correlated with serum ferritin levels.

Our present study suggests an association between serum sCD163 and PM/classic DM/CADM. The serum levels of sCD163 in patients with PM, classic DM, and CADM were each significantly higher than those in HC. In addition, serum sCD163 levels decreased significantly following treatment. Peng, *et al* also reported that serum sCD163 levels were significantly elevated and correlated with the Myositis Disease Activity Assessment visual analog scale (VAS) score in patients with PM/DM²². They also found that serum sCD163 levels decreased significantly after treatment.

For some time, sCD163 has been considered a marker of macrophage activation³⁰. Peng, *et al* reported that patients with high serum sCD163 levels show a higher incidence of CD163+ macrophage infiltration in muscle tissue than do patients with PM/DM and normal sCD163 levels²². However, increased sCD163 expression and CD163+ macrophage (M2 macrophage) activation are also closely associated with some other autoimmune diseases, such as rheumatoid arthritis and systemic lupus erythematosus^{31,32}. Thus, serum sCD163 alone cannot be used as a disease-specific biomarker.

Serum sCD163 levels were significantly different based

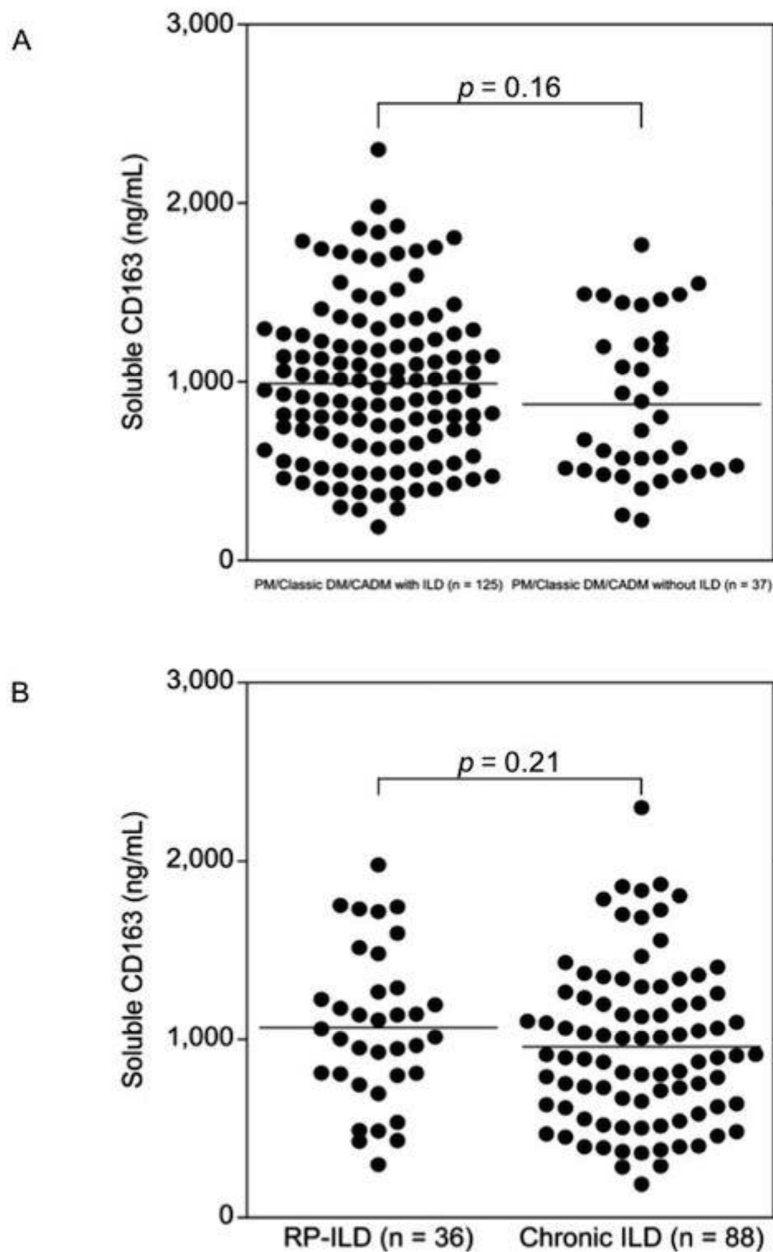

Figure 2. Associations between serum sCD163 levels and ILD. A. No significant difference was observed between serum sCD163 levels in patients with and without ILD (n = 125 and 37, respectively; $p = 0.16$). B. No significant difference was observed between serum levels of sCD163, even when the patients with ILD were categorized into those with RP-ILD (n = 36) and chronic ILD (n = 89; $p = 0.21$). P values were determined by Welch t test. Horizontal bars represent the mean levels. sCD163: soluble CD163; ILD: interstitial lung disease; PM: polymyositis; DM: dermatomyositis; CADM: clinically amyopathic dermatomyositis; ILD: interstitial lung disease; RP-ILD: rapidly progressive ILD.

on the presence of MSA in our present study. More specifically, serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies than in those without anti-MDA5 antibodies, especially those with non-MDA5 and non-ARS MSA. MSA and/or their antigen targets may have a role in the pathogenesis of PM/DM². For example, the

putative role of histidyl-transfer RNA synthetase (Jo1) in bridging innate and adaptive immune responses that ultimately result in myocytotoxicity and lung involvement has been proposed in patients with antisynthetase syndrome³³. In addition, although the pathogenic roles of anti-MDA5 antibodies are largely unknown, it is speculated

Figure 3. Associations between serum sCD163 levels and MSA. Serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies than in those with other MSA (i.e., non-MDA5/ARS; $p < 0.001$). Although serum sCD163 levels in the patients with anti-MDA5 tended to be higher than those in the patients with anti-ARS and the patients without any known MSA, they did not reach statistical significance ($p = 0.10$ and 0.12 , respectively). When the patients without anti-MDA5 antibodies were pooled, mean serum sCD163 levels were significantly higher in patients with anti-MDA5 antibodies (1194 ng/ml) than in those without (917 ng/ml; $p = 0.001$). P values were determined by the Tukey–Kramer method for multiple comparisons, whereas 2-group comparisons were analyzed using Welch t test. Horizontal bars represent the mean levels. sCD163: soluble CD163; MSA: myositis-specific autoantibodies; MDA5: melanoma differentiation-associated gene 5; ARS: aminoacyl-tRNA synthetase.

that binding of viral dsRNA to MDA5 and the consequent induction of the type I interferon response might be a possible mechanism leading to the autoimmune response³⁴. Thus, different levels of association between serum sCD163 levels and the different MSA may be derived from the respective pathomechanisms (such as innate immunity) in each MSA-associated subtype of PM/DM. Somewhat similarly, Enomoto, *et al* reported that serum sCD163 levels in patients with anti-MDA5–positive PM/DM related–ILD ($n = 14$) was “relatively” higher than in anti-MDA5–negative PM/DM related–ILD patients ($n = 34$), although the result was not statistically significant²³.

Unexpectedly, serum sCD163 levels were not specifically associated with ILD or RP-ILD in our present study. Additionally, the baseline serum levels of sCD163 in patients whose ILD deteriorated were not significantly different from those in patients whose ILD was ameliorated or remained unchanged. At a glance, these results disagree with those of previous reports. Peng, *et al* reported that patients with

PM/DM and ILD have significantly higher serum sCD163 levels than those without ILD²². Enomoto, *et al* reported that serum sCD163 levels in patients with PM/DM related-ILD were “relatively” higher than those in patients with PM/DM without ILD²³. Peng, *et al*²² used nonparametric statistics and most of the values in the 2 groups (ILD and non-ILD) were in the same range on the dot plot. As mentioned, elevated sCD163 levels are not disease-specific, and Peng, *et al* reported that serum sCD163 levels were correlated with global disease activity in patients with PM/DM and were associated with muscle macrophage infiltration²². Because sCD163 is considered a marker of macrophage activation³⁰, we speculated that macrophage activation is involved in both muscle and lung manifestations in PM/classic DM/CADM, and that serum sCD163 levels are eventually elevated in either pathophysiology.

Inconsistently with our initial hypothesis, serum sCD163 levels were only weakly correlated with serum ferritin levels in patients with PM/classic DM/CADM in our present study.

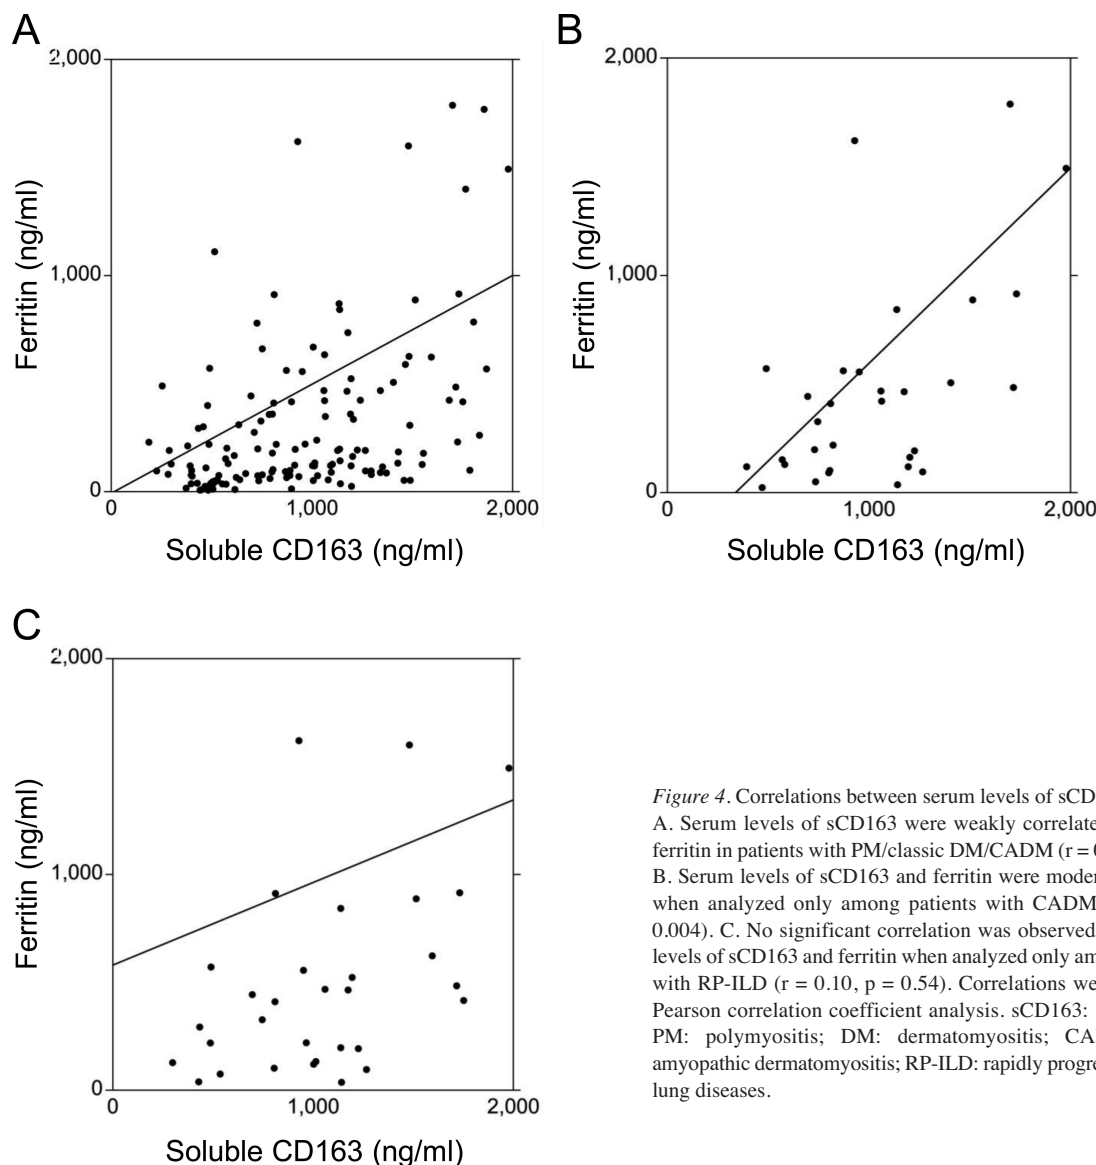

Figure 4. Correlations between serum levels of sCD163 and ferritin. A. Serum levels of sCD163 were weakly correlated with those of ferritin in patients with PM/classic DM/CADM ($r = 0.21$, $p = 0.009$). B. Serum levels of sCD163 and ferritin were moderately correlated when analyzed only among patients with CADM ($r = 0.49$, $p = 0.004$). C. No significant correlation was observed between serum levels of sCD163 and ferritin when analyzed only among the patients with RP-ILD ($r = 0.10$, $p = 0.54$). Correlations were evaluated by Pearson correlation coefficient analysis. sCD163: soluble CD163; PM: polymyositis; DM: dermatomyositis; CADM: clinically amyopathic dermatomyositis; RP-ILD: rapidly progressive interstitial lung diseases.

We reported previously that serum IL-6, IL-8, and IL-10 levels are significantly correlated with serum ferritin levels in patients with PM/DM and that they are higher in the RP-ILD subset than in the non-ILD subset or the chronic ILD subset¹⁴. A series of our previous studies^{10,12,13,14} led us to conjecture that the high levels of serum ferritin might be caused by systemically activated macrophages in patients with CADM-related and/or anti-MDA5 antibody-related RP-ILD. However, now we surmise that the hyperferritinemia in this condition is not solely regulated by macrophage activation but that other factors contribute to the phenomenon, although there is some relationship between them, as suggested by the present results. In fact, the expression of ferritin is generally regulated at both the transcriptional and posttranscriptional levels by iron, cytokine release, chemokine production, lipopolysaccharide,

prostaglandins, hormones, growth factors, second messengers, hyperoxia and hypoxia, and oxidative stress¹⁵. Alternatively, sCD163 may not be ideal for the timely assessment of macrophage activation compared to sCD163 mRNA or CD163 on macrophages.

Several limitations of our present study should be mentioned. First, the validity of our current study could be improved by using a nonretrospective design. For example, the time between the initial and second serum sample collections was too long, and there were not many samples obtained in the short-term after treatment initiation. Second, because the subjects of our present study were all of Japanese ethnicity, it is unclear whether sCD163 has a similar significance in patients of different ethnic backgrounds. Third, we did not examine the presence of CD163+ macrophage infiltration in muscle or lung tissues. Fourth, the patients were

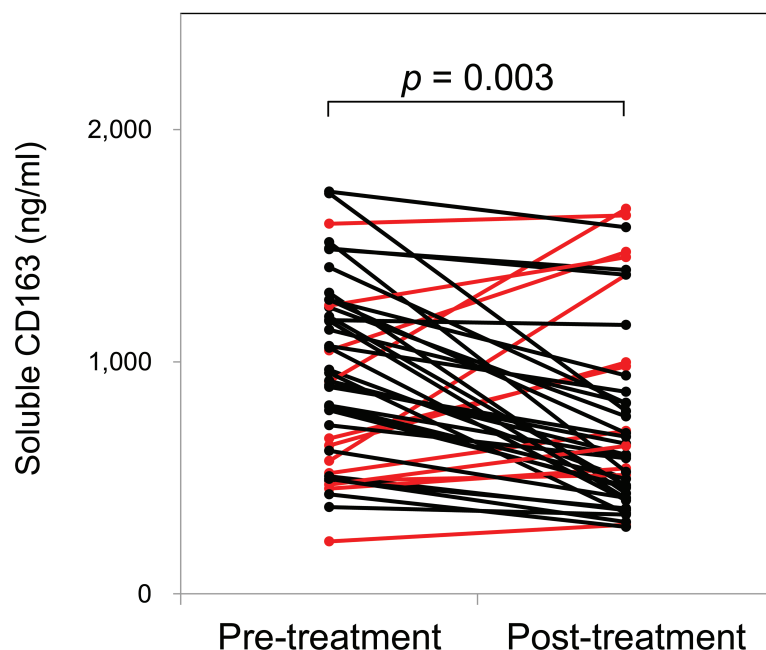

Figure 5. Serum levels of sCD163 before and after treatment in patients with PM, classic DM, and CADM. Serum levels of sCD163 decreased significantly following treatment (median decrease -26%, range -67% to 140%; $p = 0.003$). P values were determined by the paired t test. sCD163 levels increased after treatment and are indicated by red circles and lines. sCD163: soluble CD163; PM: polymyositis; DM: dermatomyositis; CADM: clinically amyopathic dermatomyositis.

older in age than those of HC. This might seriously affect the results of our present study, although there was no significant correlation between serum sCD163 levels and age among the HC or patients. Finally, we did not use the Myositis Disease Activity Assessment VAS to assess disease activity, although we investigated other factors, such as creatine kinase, aldolase, and manual muscle testing.

Our present study suggests an association between serum sCD163 and PM/classic DM/CADM, especially in anti-MDA5 antibody-positive cases. However, serum sCD163 levels were not specifically associated with ILD or RP-ILD, and the pathomechanisms of how serum ferritin works as a biomarker for CADM-related and/or anti-MDA5 antibody-related RP-ILD remain elusive.
